## THE NATURE OF CONCUSSION\*

BY

GEOFFREY JEFFERSON, M.S., F.R.C.S.

*Professor of Neurosurgery, University of Manchester; Hon. Neurological Surgeon, Manchester Royal Infirmary and Salford Royal Hospital*

The approach to the interpretation of concussion through its history presents a kaleidoscopic panorama in which succeeding generations are seen attempting to solve the same problem in the light of the scientific knowledge available to them: the same patterns of thing recur in a new setting. The first solutions were vibratory and oscillatory, and were suggested by contemporary new work in physics; they were what we should now call neurogenic, although the neurological knowledge on which any satisfactory conclusion could be reached was still to come. We shall do well to remember that each succeeding explanation offered was in accord with the best information in physics then available. However incorrect it may seem to us, it was satisfactory to a large number of contemporaries, and bore the imprimatur of the leaders of thought of the day. Some 50 years ago the oscillatory theories were abandoned in favour of a new vascular hypothesis. It was suggested by the work of Goltz, who had impressively demonstrated that the effects of shock were caused by a paralytic vasodilatation.

In 1870 Hermann Fischer, in a paper that was to become famous, discussed a case of head injury shown at a clinical meeting the day before. He asked, "What is the anatomical basis of the picture?" Various people had made suggestions, usually on gross anatomical evidence. Thus Rokitsansky (1856) had been satisfied that capillary apoplexy at the site of the injury, and maybe elsewhere, explained all the signs; and Nélaton (1847) had held a similar belief. Actually punctate haemorrhages were first described by Richard Bright (1831), who stated specifically that he did not think that they would account for the symptoms of concussion or coma. Fischer's own explanation was of a physiological kind, because in two cases that he had observed he found nothing but cerebral anaemia with congestion of the surface vessels and the dural sinuses. "You will ask," he said, "what sort of queer disease picture is this that to-day threatens the patient with the severest symptoms, all of which to-morrow will have passed completely away." He suggested, but immediately rejected, reflex vessel spasm as a possible cause of this anaemia, and replaced it with the postulate of long-continued vasoparalysis. Seven years later Ludwig Witkowski, after having first accepted Fischer's theory of vasoparalysis (and it is a remarkable error of medical bibliography that Fischer is usually credited with having postulated vasospasm), finally rejected it in favour of a neurogenic causation, its localization unspecified. Bergmann went through the same phases, while Kocher (1901) in his unnecessarily long and verbose book can be held to support all theories. Vasospasm at no time had reputable supporters,

because the physiologists had proved that there were no vaso-constrictor nerves on the cerebral vascular tree—a belief supported by Leonard Hill, and not shattered until the work of Forbes and Wolff (1928) and of M. Riser (1936) and Villaret *et al.* (1936) provided the needed correction. Ricker (1919), again, postulated a vasoparetic explanation with prestasis and focal softening. In the meantime the theory of mechanical arrest of the circulation by an instantaneous rise of intracranial pressure at the moment of injury, suggested first by Strohmeyer (1864) and brilliantly put forward anew by Trotter in England (1932), won an army of adherents. Trotter stated that cerebral anaemia was the cause of concussion, which he defined as a state of paralysis instantly induced but with a strong natural tendency to rapid and spontaneous recovery and not necessarily associated with gross damage. Longer periods of unconsciousness were attributed to contusion, but as to contusion of what (except of the brain generally, with possible local bruising and burstings) Trotter was silent. This will be recognized as a return to the neurogenic theory, although Trotter always spoke disrespectfully of those who believed in molecular commotion with widespread synaptic breaks—as well he might if the phrase is interpreted literally. In England, C. P. Symonds (1940) and I were critical of the vascular theory.

The apparent paradox arises, from a consideration of the most important contributions of the last two centuries, that in the main, however much the interpretations disagreed, the observations were correct. Although a great deal was added to the data of cerebral injury the anomaly remains that the most striking feature, the unconsciousness, was left unsolved. We shall see that the reason lay in the inability of the investigators to grasp the fact that commotion of the brain may upset its actions for much longer than a moment, the disturbance enduring longer and longer according to the severity of the concussive force. (I shall have more to say of this matter in a moment.) Nor could the majority conceive that anything below a cortical level could interfere with consciousness.

## Experimental Effects of Concussion on the Brain-stem

The effects of injury showing themselves so often by alteration in the pupils, in the frequency and depth of respiration, in the pulse rate, blood pressure, and low-level somatic reflexes (the corneals, the pharyngeal, laryngeal, and swallowing), focused the attention of some workers on the brain-stem and on possible means by which such a low-level injury could come about. Hence sprang Duret's theory of cerebrospinal fluid shock, which provided a theoretically good explanation of the reason why a blow on the vertex should injure the vital bulbar centres; and he, together with Koch and Filchre (1874) and especially Polès of Belgium and Miles of Edinburgh, published convincing experimental evidence that low-level disturbances even as caudal as the spinal cord (in which gross lesions were more often found than many remember) did

\* Read by invitation at the American Neurological Association's Annual Meeting, New York, May 7, 1943.

actually occur. Gavin Miller (1927) repeated much of this work, and was able to cause concussion in the heartless frog as had Schiff, Goltz, and Witkowski before him. The problems were restated and retested by Denny-Brown and Ritchie Russell (1941) in a most important experimental series in which the evidences of brain-stem paralysis were proved to be well founded, with the entirely novel discovery that concussion could much more easily be produced if the head were free to move when it was struck. The essential factor was the suddenness of the acceleration imparted to the head and, in different circumstances, of the deceleration. The immediate alteration in respiratory rhythm, in pulse rate, blood pressure, pinna and corneal reflexes found by others, were again observed. A vital fact was that concussion could be produced without deformation of the skull—a rebuttal of the common surgical pictorial representation of indentation of the skull compressing the brain. None the less, the active cause remains a sudden application of energy to the brain. It is important to note that Denny-Brown and Russell had been able to produce concussion in decerebrate animals. These experimenters had nothing new to offer on the cause of the most impressive feature of concussion—unconsciousness itself—since their animals were either anaesthetized or decerebrate. We can safely leave the fundamentals of concussion other than this last as resting on a firm basis of experimental proof linked with clinical observation, and conclude that whatever alterations in cerebral blood supply either accompany or follow a concussive blow are secondary or epiphenomena, and that the prime cause is a paralytic effect on the neurons of which the brain mass is composed, including those of the brain-stem.

#### Unconsciousness or Traumatic Stupor

The question is, What part is played by the cerebral hemispheres, the cortex, and the deeper nuclei in the concussion or contusional syndrome? The majority of writers have assumed that consciousness is mediated by the cortex, and it will be immediately conceded that of full consciousness in the psychologist's sense this is certainly true. What is more, the occurrence of fits, often of focal type, the development of paralysis and of post-traumatic mental disorders, and the discoveries made at necropsy all certified that cortical and sub-cortical lesions of various degree and in various situations could sometimes, but not always, be found at high levels of neural integration and were not to be denied their importance in the total clinical picture. Are these the cause of stupor? The experiments of Tillman (1899) on the sliding movements between grey and white matter because of differences in their specific gravity, the cover-glass experiments of Ferrari in Kocher's laboratory, searches into the histology of the cortex after injury (Jacob, von Holder, 1904), all attest this concentration of inquiry on the cortex. More recently Greenfield (1938) demonstrated the demyelination that often follows severe injury. All these studies, save Greenfield's, ended without conclusions of a convincing kind, because the inquirers failed to realize what seems to be fundamental fact—that injury, that contusion, paralyzes nervous actions without the necessity for the effects of the contusion to be either macroscopically or microscopically visible, as was correctly stated by Trotter in his classical definition. The proof lies in the vigorous scrutiny of the facts of concussion itself and of contusion of the spinal cord and peripheral nerves. Laboratory work on the passage of impulses along axons (Erlanger) and on transmission at the synapse agrees that these are easily disturbed without gross alteration in structure. There is much that we must learn about the living conditions of the neuron, single or in vast communal partnership, after injury; physiological analysis by electrical methods holds out more hope of success than anatomical study. We should become better able through biophysics and micro-chemistry to demonstrate electro-chemical deviations from normal under injury.

Turning to clinical study of concussion or contusional cases, we are presented with material which is almost too rich, coloured as it is by individual differences of the patients' personalities and behavioural possibilities, and we are driven to the conclusion that there is no single fact or any group of facts which will tell us the course of unconsciousness in head injuries without confirmation from other sources. I have long believed that the classical stupor-recovery-stupor sequence

of intracranial bleeding might hold the key to the problem. I know now that it does so.

There can at this date be little doubt that traumatic unconsciousness is produced by a low-level lesion—hypothalamic and brain-stem. Suggestions to that end have been made in the past by Heubel and by Breslauer (1914) in favour of the fourth ventricle, Knauer and Enderlen (1922) for the mid-brain. B. Heubel and Witkowski found that when they opened the skull of a frog and touched the fourth ventricle with the head of a needle the animal, after showing evidence of pain, fell into a completely comatose condition lasting a longer or shorter time; the same result could be got in rabbits. Witkowski had witnessed the accidental injection of novocain through foramen ovale into the posterior fossa in anaesthetizing human trigeminal nerve—an act which produced stupor, experiment he found that the injection of fluid into the posterior fossa of animals also had that effect. Something more than tentative support to the doctrine of consciousness as a low-level affair has been adduced for non-traumatic cases by Penfield (1938) and by J. C. White (1940). In this J. G. Greenfield also suggested it. Not only have animals rendered unconscious by experimental injuries to the end of the fourth ventricle at pontine level but, what is more convincing, injuries inflicted on man on comparable areas, especially in attacks on acoustic neuromas, are usually attended, when fatal, by unconsciousness from the moment of operation. It is in fact one of the most striking of neurosurgical phenomena that unconsciousness can be so readily produced by disasters in the posterior fossa and that ventricular drainage, which reduces the hemispherical pressure to zero, has no effect in restoring consciousness though the dynamics of the cerebral circulation and hemispherical tissue respiration must have been restored to normal. Nor does pressure of brief duration, a generalized cause unconsciousness, as Browder in pain has shown in the human. I can support that observation. That it may do so in time none will deny, but then for special reason that pressure sustained for some hours or days causes a prolapse of the temporal lobe on the compressed (or of both lobes if the compressing agent is medial more distant) into the tentorial hiatus. Here a cone is formed which compresses the diencephalon and rostral end of mid-brain, and unless this can be relieved by the appropriate surgical measures unconsciousness will continue until autolysis or breakdown causes death. This is the explanation of the fact that surgical mortality chiefly occurs in cases with unrelieved pressure cones or when bleeding into the mid-brain has already taken place. There is little doubt that a cone at this level is more frequent and more dangerous (because less relieved) than the better-known one at the level of the falx and the great sylvian fissure.

#### Focal Lesions causing Stupor

I have said that evidence on the localization of consciousness (and I shall shortly return to a statement of its nature) is produced from other sources. Mention has been made of a fact that a posterior fossa lesion may cause unconsciousness. The notion that the stupor is caused by so severe a lesion back of the c.s.f. in the ventricles that cortical anaemia is destroyed by the observation that the state may persist in intraventricular pressure is reduced to atmospheric. It is that puncture may relieve, but the vital point is that it does not necessarily do so and that the patient may die with nothing above the tentorium, or at least above the hypothalamus, apparently normal.

Clean-cut examples of brain-stem or hypothalamic lesions causing coma are presented by the following cases:

**Case 1.**—A. B., aged 48. Admitted Neurosurgical Service, Chester Royal Infirmary. Referred by Dr. O. M. Duthie to the Royal Eye Hospital Dec. 10, 1942, on account of protrusion of eye for 3½ months. The local signs are not important for the present discussion. A right-sided bone flap was turned down and the skull unroofed, with the discovery of a small resistant mass in the middle of oedematous orbital contents. It was judged to be non-neoplastic and the operation was concluded as an orbital decompression Naffziger type. The patient's pulse was rapid throughout the operation. She did not recover consciousness, and died 48 hours later in hyperthermia. Her pulse rate ranged between 174 and 180 respirations in the 40s and 50s and a temperature that varied between 99.6° and 104° on the first day and between 102° and 105°

Second. Occasionally she looked as if she might be about to wake up and half opened her eyes, giving the impression that she might be arousable and might speak if she could be sufficiently interested. All efforts to make contact failed and stupor returned.

The problem is, Why had this patient died? I suggested that a mid-brain or periventricular haemorrhage caused by anoxia in a long nitrous oxide anaesthesia might be the cause. However, at necropsy it was found (1) that the nodule in the orbit was a thrombosed aneurysm of the ophthalmic artery; (2) that there was no extradural clot; (3) that externally the brain was completely normal; (4) that she had died from the local compressive effects of the rupture of a second aneurysm in the cerebellar vermis with blood-clot plugging the iter (see Fig.).

stupor. These cases demonstrate the prime importance to consciousness of intact integrative pathways in a vertical direction, and demonstrate also that anatomically undamaged connexions in and between the hemispheres themselves are not sufficient to maintain consciousness. This is in some ways a surprising conclusion, but there is no doubt of its truth. Other examples might easily be adduced, but for the moment these will suffice while we turn to the essential point—the nature of this stupor, this state that we call unconsciousness.

### ✓ The Nature of Unconsciousness

The description of diseased or abnormal states by delineating them as the reverse of a defined normal is not one which has commended itself to medical science. This holds true of definitions of consciousness and unconsciousness. We might accept the statement that consciousness is a state in which man (or animals for that matter) respond to environment in a manner which shows insight (cf. Penfield and Erickson, 1941). It is true to say that unconsciousness and the stages of recovery from it, even when they are long-drawn-out, can be comprehended by the reverse of the foregoing—that the patient does not to this or that degree show insight into the problems which his environment sets from day by day or hour by hour; but the statement lacks the necessary crispness. It would be more helpful to define unconsciousness, whether traumatic or otherwise, by a new term which designated more pointedly its nature, its pathological status in terms of neurophysiology. When we watch a patient recovering from concussion we see him sleeping most of the day and night, disturbed at first by only the most intense stimuli, aroused not by thirst or hunger but principally by the pain of bladder distension, made restless by it and sometimes also by pains in the head or elsewhere which he does not understand, cannot analyse. As he recovers, sleep is less compulsive; insight into his state increases. Conversely, when we watch, as occasionally we must, a patient dropping into coma, the picture is even more clearly derived from sleep. At first susceptible to both internal and external stimuli, interest is lost in food, incontinence develops, until stage by stage the hypersomnic periods merge into complete negativism and an unrousability from which there is no reveille. Step by step alterations in pulse rate, thermal control, and water balance take place which culminate in metabolic disaster, local or general, and death.

### Parasomnia

We approach closer to the facts of clinical observation if we speak of unnatural or, in the case of concussion, of traumatic sleep rather than of unconsciousness. Traumatic stupor is a better term than unconsciousness because it has for most of us a certain sleep connotation. There is an advantage in inventing a new term to overcome these difficulties. Something is needed with a sleep meaning but indicative of a condition different from ordinary sleep. The best that suggests itself to me is "parasomnia," a state in which there is no response to stimuli, verbal or mechanical, except those of a reflex nature. In other words, there is no response showing insight into or analysis of the problem set by the stimulus—at least no more than there is in a sleeping person. Variations in the picture can be regarded as the arrest of a moment of awakening and the giving to it of duration. This makes it a completely abnormal condition, and although we may for convenience regard it as an instantaneous freezing of a normal state, this must not blind us to the fact that it is pathological and associated with other abnormalities which further testify to that fact. Whatever words we use we should in future think in terms of sleep and wakefulness. The toekings, nose and body rubbings, mutterings, and unruliness occurring with some head injuries show that cortical actions continue, and compare with those observed by Kleitman (1939) in his studies of sleeping beings. And there is no doubt a high-level disturbance or inhibition of the cortex, partial or complete. But cortical lesions pure and simple do not seem to produce it, nor do massive excisions of the cerebral lobes, as I can well testify. No completely satisfactory human decortication is ever brought about by disease, and certainly never by surgery. We lack that piece of evidence. Yet a small central and basal injury certainly does so. This brings us, if the interpretation

This is a convincing example of the unconsciousness caused by a lesion at infra- and per-tentorial level; the fact that it caused death is less remarkable than its effect on total behaviour.

Case 2.—A woman aged 32 was referred by my medical colleague Dr. A. H. Holmes as a case of pituitary adenoma. What was unusual was the severity of her pain and the fact that she was brown and ill. Operation was performed and an unusually vascular chromophil adenoma cleared out easily. The patient failed to regain consciousness and died, much as did the previous case, in hyperthermia. Necropsy disclosed no contusion of the brain and an average small amount of subarachnoid blood in the basal cisterns. On section of the brain the cause of death was found to be a local clot some 3 cm. in diameter in a suprasellar situation occupying the third ventricle. Once more the essential fact is not that the patient died but that a localized clot in this situation caused stupor.

Case 3.—Mrs. G., aged 31, had the usual signs of a left-sided acoustic neuroma. It was evident from the neurological disturbances that this tumour was of very considerable size. At operation, Jan. 10, 1942, an exceedingly large tumour was subtotally removed, its complete extirpation proving to be impossible. During the manipulations her blood pressure rose to 180, the pulse falling to 50. Five hours after the operation she was moving her arms but could not rouse. She perspired freely and her face was flushed; there was a general vasomotor relaxation. The patient died in this condition 18 hours later with shallow rapid respirations and some evidence of pulmonary oedema. At necropsy the remains of the tumour were found to extend into the hiatus tentorii, and there were discrete haemorrhages in the mid-brain and pons. The cerebral hemispheres were in all respects normal.

In Cases 2 and 3, so far as could be observed, the cerebral hemispheres and the anterior hypothalamus were normal; although all the patients made movements they remained in

which I have given is accepted, head on to the localization of the sleep centres variously placed in the anterior periventricular grey matter of the third ventricle or deeper in the posterior hypothalamus, in the anterior hypothalamus (meaning these areas plus some so far indefinable parts of the basal ganglia), or in the upper pons, or in all (von Economo, 1926, 1930; Fulton and Bailey, 1929; Ranson and Magoun, 1939; Globus, 1940; White, 1940). Nothing could be clearer than the fact that lesions in these areas have an effect on consciousness. Neurosurgery and neuropathology have done much to confirm the truth of observations made in the laboratory. And since lesions in these areas cause stupor and hypersomnia we cannot deny that trauma most probably produces its effects on consciousness in the same areas. It would be ingenuous to believe that there is a nucleus which controls sleep. The obtundation of consciousness must be a highly complex action in which the whole nervous system co-operates. It seems more logical to postulate a "waking centre" (and by "centre" I do not mean a cluster of cells but a circumscribed brain area, injury to or stimulation of which causes certain constant results), damage to which would result in hypersomnia, ending in that mixture of sleep and illness which I have just called parasomnia. Although the area of these waking centres is roughly known we cannot always demonstrate injuries in them. As Symonds pointed out, it is no more "required" to show histological changes than it is in post-epileptic stupor and in Todd's post-epileptic paralysis. Denny-Brown and Russell and their forerunners all showed that animals could be killed without verifiable alterations in nervous structure. But it is a fact that mid-brain, hypothalamic, and pontine lesions can be demonstrated in some persons who die from injury as well as in those who die from tumours. The limits of the region concerned have still to be accurately mapped. Disturbances of the lower closed part of the medulla oblongata seem to be less able to disturb consciousness than those in the upper half of the fourth ventricle, but even that is unsure. The rostral extent is even more difficult to give with precision; it might extend into the palaeocerebrum wide of the third ventricle.

It would be a valuable step if we knew the behaviour not only of a single cell under trauma but of many cells, their rate and regularity of firing, the "boosting" required, the changes that occurred in cell respiration, and enzyme requirements. Further, we shall need to know the effects of trauma on electrical potentials and fibre transmission at different levels of the brain from the cortex to the cord and, if possible, at all levels at the same time. A valuable start was made by Dennis Williams and Denny-Brown (1941) and is being further elaborated by Earl Walker. The e.c.g. pattern is often very similar in sleep to that seen after concussion; there is the same disappearance of fast activity and the same appearance of high-voltage slow waves. As for the circulatory disturbances after head injury, there is a good deal of evidence that these happen in the severer cases. But whether they are occasioned by the stretching of the vessel walls by the agency of the momentary compression of contained blood, or whether they are the result of disturbance of a vasomotor centre or centres arise from altered oxygen and carbon dioxide tensions, we have still to learn. The experiments of White show that there is a slight increase in brain mass after an injury, but oedema of a severe grade seems to be limited to the periphery of areas of actual contusion (Greenfield). We have to regard cerebral pathology after injury as a moving picture altering from day to day. Beyond a certain point there may be a progressive break-up of integration that must eventually be measurable in terms of cell metabolism as well as the transmission of impulses. Some petechial haemorrhages certainly arise secondarily, and are not the immediate effects of the violence. Changes in the vessel walls are visible within a few hours after injury, and these must effect the filtration of plasma elements and finally even of erythrocytes.

If we agree that the major phenomena produced by concussion are not primarily cortical, and are usually recovered from because in the majority of cases the disturbance is a physiological one without gross and persistent underlying alteration in structure, we can more properly understand that the results should so often be good and may be less inclined to accept easily a pessimistic view in prognosis.

### Cortical Activities

The foregoing account has but lightly touched activities of the cortex in concussion, and maybe importance has been unduly minimized. We know of chiefly from psychological study and from e.g. analysis methods which are only in process of correlation. Reference has been made to the effect of a mid-brain lesion in interrupting integrative impulses in caudal and rostral directions and a profound effect that such a block seems to have on what have been regarded as largely intercortical activities. The facts are fully in accord with Kleitman's views on the state of sleep. A similar conception underlies the state of akinetism described by Cairns, Oldfield, Pennybacker, Whitteridge (1941). This again is a negative state affecting both intellectual and emotional tone, and in the one described case on which their paper depends its basis in a third ventricle lesion was well attested. Observations lead me to believe that parasomnia and akinetic mutism are the same thing, but that many patients with cerebral contusion or with tumours can go through this mute state on the way to recovery or, conversely, towards coma. Speed of recovery may prevent its detection or development as a definable condition. For example, in two of the clinical cases recorded above there were moments when the state resembled akinetism alternating with restlessness and mutism and somnia. The difference lies in the sleep propensities (states); it is the dominant factor in the one, not so in the other. Nor does it seem probable that akinetic mutism any more to be separated from general physical disorder is parasomnia. It must be made clear that I do not regard the latter as a purely mental state; it is something more than that. The recognition of these two states, if confirmed by observation by others confirms their validity, would be a step in the unravelling of behavioural peculiarities at a level of psychological functioning than has so far been explored.

The long-lasting mental confusion, the Korsakov syndrome, the patchy or incoherent memory, which persist for months or even weeks after some severe head injuries, can be explained by disturbances of total brain functions which though not certainly, be due purely to cortical blocks. Far they derive from actual anatomical alteration we know. Common sense seems to say that they must have dependence, but a certain amount of agnosticism is allowed. Occasionally the post-traumatic mental state resembles that after bromide intoxication and no doubt from other agents. We do not yet know for how long the interplay of neuronal constellations may be disordered without damage in the sense in which we mean it at present. Perhaps in the future, advances in the technique of recording potentials will reveal abnormalities in the quality, quantity and timing of cell discharges and axonal conduction; a chemical or enzyme background of abnormality indicating the injury, disturbing the co-ordination of those "self-nourishing electrical leaks" (as Sherrington calls them) that underlie cortical activities. Only in some such manner can one postulate a cause for that Jacksonian dissolution of nervous integration that signifies in different ways, at different stages, the effects of concussion. We suspect, though it is not yet proved, that general cerebral contusion causes a disturbance in the blood supply which may conduce to abnormality necessarily originating it.

### Trauma as a Disease Process

In conclusion, no statement on concussion would be without mention of a matter which has so far attracted little comment—the cause of death in those who survive immediate injury. Necropsy material is insufficiently reported because we are dealing with a functional disorder. Explanation has run into wrong channels through the discovery of abnormalities of action must always be accompanied by gross change (and in that term I include microscopic discovery of cortical injury (though much less than the can inflict with impunity), the finding of subarachnoid haemorrhage (though no more in amount than many with aneurysms survive), the presence of relatively small quantities of subdural blood, are not enough to account for death

should be the last to deny that all of these things can cause death when they are severe enough. But it must be strongly asserted that the findings in human beings are often disappointingly small—disappointing, that is, to the mind which is prepared only for anatomical findings. Yet it is not these things, nor the petechial haemorrhages of classical times, which smell us most; it is rather their variability or their absence. To find nothing would be in line with the most informative of experimental evidence. This raises the question as to how it can come about that an initial lesion severe enough to cause cerebral paralysis can be survived though death occurs hours or days afterwards. There is no question about the fact that this can and does happen; and it is certain, it is sure. Only one explanation suggests itself—that an injury sets going a self-propagating event that leads sooner or later to death. It would be a mistake to draw too much on analogy, and any explanation must be regarded as both speculative and tentative. But death from burns, from fractures, and from haemorrhages will serve as shorthand notes indicating at least a parallelism. We can only speculate at the moment on what the answer will be in the case of cerebral concussion. It is the fate of all of us to watch patients with cerebral lesions dying from something characterized by tachycardia and cardiac irregularity, from upsets of thermal regulation, from metabolic disturbance which we have not yet found a means to study properly, from something that bears the hall-mark of a disease process as much as, say, pneumonia. The old beliefs in the omnipotence of the bulbar centres has been corrected by the discovery of the vital centres re-representing them at and above the tentorial level. Conceivably it may become possible to demonstrate alteration in oxidation-reduction mechanisms in this area which will afford an index of cellular pathology. It seems legitimate to suppose that the physical effects of injury lead to affection of at least one enzyme system, the lack of which can for a time be repaired by the altered energies of others, which also in turn give out. Thus, step by step, dissolution comes about. Only in such a way can temporary survival with final extinction be given a cause. And it will be recognized that the level at which all of these happenings occur is in the more primitive but still no doubt extremely complex and largely integrated neural mechanisms considerably below cortical level.

#### Conclusion

Although the beliefs expressed above have minimized the importance of the cortex in the picture of concussion, it is not my belief that cortical disturbances are absent. Electrical records clearly show that they are frequent; while some patients, by confusion, confabulation, and lack of insight (sometimes for many days after return to consciousness), demonstrate that the whole brain integration continues to be disturbed. It is not possible at the moment to do more than speculate on the causes and mechanisms of this dysfunction. The real point that I have wished to examine is the nature of unconsciousness, and I have endeavoured to show that there is a body of evidence attesting to its production in a relatively focal manner, and that the focus is not, as has been so generally believed, in the cerebral cortex.

## NUTRITIONAL DEFICIENCY IN THE PATHO-GENESIS OF DISEASE\*

BY

JOHN YUDKIN, M.A., M.D., Ph.D., F.I.C.

Lieut. R.A.M.C.; formerly Sir Halley Stewart Research Fellow at Dunn Nutritional Laboratory, Medical Research Council and University of Cambridge

More and more has the role of vitamin deficiency claimed our attention in recent years, and a variety of diseases and syndromes have been treated with a vitamin or a combination of vitamins. Frequently the reasons for doing this are obscure and the results of the treatment equivocal; and the relation between the condition and vitamin deficiency often remains difficult to assess.

Nutritional deficiency may be responsible for the production either of a recognized disease, of hitherto unknown aetiology, or of obscure signs and symptoms in an individual. For example, claims are sometimes made that vitamin deficiency plays a part in the production of renal lithiasis (Higgins, 1935) and certain muscular dystrophies (Bicknell, 1940). Again, a patient is seen with an unusual form of keratosis of the skin, or with oedema which does not easily respond to ordinary therapy, or with a sore tongue with few other signs or symptoms, or with an unusual type of subcutaneous haemorrhage: to what extent are vitamin A, vitamin B<sub>12</sub>, riboflavin, and vitamin C respectively implicated in the production of these disturbances in the individual?

In this paper I shall consider certain general principles which might act as a guide in the evaluation of the part played by vitamins in the causation of disease. Just as we use Koch's postulates in determining the role of specific bacteria in causing disease, so we may lay down the following criteria for assessing the role of nutritional deficiency in causing disease: (1) It should be possible to demonstrate the existence of a deficiency of the nutrient; (2) deficiency of the nutrient should result in the production of the disease; (3) the disease should be cured by replacement of the deficient nutrient. To satisfy each of these criteria,\* evidence may be collected in several ways:

#### Diagnosis of Nutritional Deficiency

##### Criterion 1.—Existence of deficiency

- A. General evidence of deficiency
  - (i) Evidence of inadequate diet
  - (ii) Evidence of defective absorption
  - (iii) Evidence of increased utilization
- B. Specific evidence of deficiency
  - (i) Laboratory tests for specific deficiency
  - (ii) Clinical tests for specific deficiency

##### Criterion 2.—Deficiency as the cause of the condition

- A. Evidence from animals
- B. Evidence from human beings

##### Criterion 3.—Cure of condition by correction of the deficiency

Therapeutic test

#### Criterion 1: Existence of Deficiency

The first criterion is that there should be evidence of nutritional deficiency in the condition. This evidence may be either general or specific.

##### A. General Evidence of Deficiency

There may be evidence of a deficiency in any part of the pathway between the nutrient and the tissues.

##### (i) Evidence of Inadequate Diet

A dietary history is an essential first step in diagnosis. The following conditions are especially apt to lead to an inadequate diet.

(a) *Low Income Levels*.—On the whole, foods which are good sources of vitamins are also more expensive; cheaper foods supply mainly calories (Orr, 1936).

(b) *War*.—Wartime measures, such as the introduction of the national loaf and the vitaminization of margarine, together with rationing, the price control of foods, and the distribution of cheap or free milk and fruit juices, have decreased the disparity between the diets of various classes. Nevertheless, there are many who still

\* Based on a paper read at a meeting of the Nutrition Society (Scottish Branch) at Glasgow, Aug. 26, 1942.

† Certain exceptions to the fulfillment of these criteria are discussed below.

cannot afford to buy the whole of their meat or bacon ration or to spend much on vegetables. Moreover, since war leads to restricted imports, to a decreased man-power for food production, and to the destruction of crops and other foodstuffs, it may be a potent cause in the production of deficiency disease.

(c) *Season*.—An example of the part played by this factor is the low level of vitamin C in foods in the spring and early summer. It is therefore at this time that the effects of its deficiency are most likely to be seen (Harris, 1942).

(d) *Geography*.—Differences in food production and dietary habits lead to the classical examples of geographic endemic deficiency disease such as the association of beriberi with the consumption of polished rice and pellagra with the consumption of maize.

(e) *Special Diets*.—Possibly the commonest cause of adult scurvy in Britain is the consumption of a too rigid "gastric" diet by patients with peptic ulcer, without adequate precautions for assuring the supply of vitamin C (Harris *et al.*, 1936). Also, beriberi has been reported in food cranks who have lived on a diet containing excessive amounts of highly purified carbohydrates. It is possible that the well-known occurrences of pellagra in mental hospitals are partly due to the perverted food habits of the patients.

(f) *Institutions*.—Outbreaks of deficiency diseases are often reported from institutions; nor is this surprising in prisons and asylums, where the allowance for food may not be sufficient to supply even the necessary calories. But the unique nature of institutional feeding may result in an inadequately balanced diet even if economic considerations do not restrict the choice of food. In the first place, the food and its preparation, for a large number of people, are in the hands of a few individuals, who may easily, through ignorance or lack of care, be responsible for a diet of poor quality. Secondly, the preparation of food on a large scale introduces new problems in connexion with the preservation of its nutritive quality; it requires special care, for example, to preserve the vitamin C (King *et al.*, 1942).

## (ii) Evidence of Defective Absorption

(a) *Water-soluble Vitamins*.—Many affections of the gastrointestinal tract appear to decrease the absorption of vitamins of the B group. Hyperemesis gravidarum (Strauss and McDonald, 1933) and alcoholic gastritis (Minot *et al.*, 1933) are often associated with deficiency of vitamin B<sub>1</sub>; in the latter condition there is probably a second factor in the diminished intake of the vitamin in the diet. Gastrectomy, colitis, and intestinal obstruction often lead to a complete deficiency of the vitamins of the B<sub>2</sub> group (B.M.J., 1942).

(b) *Fat-soluble Vitamins*.—The absorption of these substances is bound up with the absorption of fat. In obstructive jaundice, in which the absorption of fat is decreased, there is diminished absorption of vitamins A (Brees and McCoord, 1940) and K; it is known that the difficulty in controlling haemorrhage in obstructive jaundice is due to this "conditioned" deficiency of vitamin K (Warner *et al.*, 1938a, 1938b). The effect of large doses of liquid paraffin in hindering the absorption of carotene is another example of induced defective absorption of fat-soluble vitamins (Rowntree, 1931).

## (iii) Evidence of Increased Utilization

(a) *Pregnant and Lactating Women*.—In some degree pregnancy and lactation increase the demand for all the nutrients, including the vitamins. Osteomalacia and beriberi are examples of deficiency disease which may be precipitated by these increased physiological needs.

(b) *Heavy Manual Workers*.—It is likely that the utilization of many nutritional factors is greater with increased physical exertion. Many Europeans consume diets which probably contain no more vitamin B<sub>1</sub> than those consumed by many Chinese; the high incidence of beriberi among the latter is probably associated with the heavy work which they do.

(c) *Fever*.—There is apparently an increased destruction of vitamin C and possibly other vitamins during fever (Abbasy *et al.*, 1936, 1937; Harris *et al.*, 1937). Usually the primary condition, such as tuberculosis or rheumatic fever, overshadows deficiency of the vitamin, but this deficiency may play a part in delaying recovery or in the persistence of certain signs.

## B. Specific Evidence of Deficiency

This evidence may be obtained either by laboratory tests or by clinical tests.

### (i) Laboratory Tests for Specific Deficiency

(a) *Vitamin Concentration in the Blood*.—The determination of the blood concentration of vitamin A, B<sub>1</sub>, or C has often been used to assess the nutritional level in respect of these factors. The results of such investigations, however, appear to depend to a large extent on the immediate past diet, and give less indication of the more permanent nutritional state. A very short time on a diet high in vitamin A, for example, will lead to high blood levels although the subject still shows signs of deficiency (S. Yudkin, 1941); the converse is also true. To some extent this has been recognized with

vitamin C: estimations on the whole blood or plasma have been found to be less reliable as indices of vitamin C nutrition: estimations on the white-cell layer (Heinemann, 1938, 1941).

(b) *Vitamin Excretion in the Urine*.—With the water-soluble vitamins, the amount excreted in the urine, and especially the rapidity with which large doses are excreted, have been useful methods for detecting slight deficiency (Harris and Ray, 1935). Such tests have been employed mainly with vitamin C, but they are also proving of value in the diagnosis of deficiency of vitamin B<sub>1</sub> (Banerji and Harris, 1939; Wang and Yudkin, 1940) and nicotinic acid (Kodice and Wang, 1941).

(c) *Functional Tests*.—Slight deficiency of a vitamin often causes physiological or biochemical changes, which may be detected by the use of special techniques. Impaired dark-adaptation, capillary fragility, or a rise in blood phosphate has been used to demonstrate mild deficiency of vitamins A, C, and D. A rise in pyruvic acid in the blood or urine, particularly after the ingestion of glucose, has been suggested as a means of recognizing early deficiency of vitamin B<sub>1</sub> (Banerji and Harris, 1939). Unfortunately these methods, although of great value, have been used uncritically by some workers, and the published results have often been conflicting. The main reason for this is that tests such as dark-adaptation and capillary fragility appear superficially simple to employ, but in reality require most careful application and rigid control (Hecht and Schlaer, 1938; J. Yudkin, 1941; *Lancet* 1942; Yudkin and Ferguson, 1943).

### (ii) Clinical Tests for Specific Deficiency

Clinical examination may reveal signs which are similar to those seen in the known deficiency disease, or they may be found in association with such signs.

(a) *Signs Resemble Those in Recognized Deficiency Disease*.—The realization that the neuritis of alcoholism and that of pregnancy toxæmia were due to deficiency of vitamin B<sub>1</sub> came, partly at a rate, from the recognition of the similarity between these and the signs of mild "dry" beriberi. But this type of evidence must be used carefully: it has led, for example, to the quite illogical use of vitamin B<sub>1</sub> in neuritis of many sorts, including sciatica (Roch and Sciclounoff, 1938).

(b) *Signs Associated With Those of Recognized Disease*.—*Individuals*.—In individuals with signs of a deficiency disease the presence of other signs whose pathogenesis is obscure suggests that these are also due to the same deficiency. Thus obscure neurological signs found in Cingalese prisoners appear to be due to deficiency of vitamin A, since other signs of A deficiency—e.g., phrynoderma—were also present; moreover, beriberi is uncommon in Ceylon, and that the neurological signs were unlikely to be caused by deficiency of vitamin B<sub>1</sub> (Nicholls, 1935). In view, however, of the frequency with which multiple deficiency occurs, caution must be used in interpreting such findings. Until recently, for example, it was thought that some of the changes in the skin and tongue in pellagra were due to the lack of the pellagra-preventing factor. Only after the latter was isolated as nicotinic acid was it found that the signs were due to a superimposed deficiency of riboflavin (Yudkin, 1937-8; Sydenstricker, 1941). Incidentally, this type of evidence can be used in the opposite way: if certain obscure signs are found in association with signs of a deficiency disease it is unlikely that they are due to this deficiency. Thus it was at one time suggested that disseminated sclerosis and subacute combined degeneration of the cord were due to deficiency of vitamin A, but the fact that other signs of this deficiency are rarely found in these conditions makes it unlikely. *In a Population*.—If a deficiency disease is common in a certain population the same deficiency may often be the cause of other less well defined conditions. Much of so-called toxæmia of pregnancy in Hong Kong, where beriberi is common, has been shown to be due to deficiency of vitamin B<sub>1</sub> (Nixon, 1942).

## Criterion 2: Deficiency as Cause of Condition

Our second criterion—that the signs should be reproducible by deficiency of the suspected factor—may be applied either in human animals or in human beings.

### A. Evidence from Animals on Experimental Deficient Diet

Analogy from animal experiments has proved very useful in the recognition of signs of human deficiency. The production of haemorrhage due to lack of vitamin K (Dam and Schönheyder, 1932) and vascularization of the cornea due to lack of riboflavin (Wolf, 1937; Bessey and Wolbach, 1939) are examples of this. On the other hand, such analogy must not be carried too far, as has been done with vitamin E and the production of neuromuscular disease (Bicknell, 1940) or vitamin A and the production of neurological disease (McLanby, 1934).

### B. Evidence from Human Beings on Experimental Deficient Diet

As might be expected, there are many difficulties in conducting such experiments on anything like an adequate number of sub-

It is not surprising, therefore, that few have been reported. It could be expected that the results would be very convincing, but in fact the conclusions reached are often conflicting. Thus some workers have claimed that a dietary deficiency of vitamin A produces a deterioration in dark-adaptation within a few days (Hecht and Mandelbaum, 1940), while others have found no change after six or six months (Steffens *et al.*, 1939). It is possible that these divergent results are due to such factors as differences in individual requirement, differences in the stores of the vitamin before the experiment is begun, and differences in the composition of the deficient diet—that is, the possible concurrent existence of other deficiencies.

### Criterion 3: Cure of Condition by Correction of Deficiency

#### Therapeutic Test

Wherever possible, the effect of correction of the supposed deficiency should be observed. Here again, however, it is unfortunately true that many reports in the literature of the cure of symptoms and signs by the administration of a vitamin are vitiated by the failure to observe certain general principles. The commonest source of error is the use of inadequate controls, and especially the failure to allow for spontaneous remission. On the other hand, if a deficiency really exists, negative results may follow the administration of the missing factor. Often this is due to inadequate dosing or to defective absorption; in such cases large doses, if necessary given parenterally, must be tried. Failure to cure may be due to the fact that the pathological process has progressed so far; it is not always possible, for example, completely to cure longstanding peripheral neuritis of beriberi by the administration of vitamin B<sub>1</sub>.

A less well recognized reason for the failure to achieve improvement by the correction of an existing deficiency is the simultaneous existence of other deficiencies. It is often overlooked that a diet deficient in several factors, that the administration of only one of these may produce no improvement, and that this does not imply that the diet must necessarily have been adequate in this factor. For example, Peterhead children on diets undoubtedly deficient in vitamins A and D as well as many other nutrients were no better than the controls when given these substances (Sutherland, 1934). It was accepted in this experiment that deficiency of one or more other nutrients was the limiting factor in preventing improvement. Similar results were recently obtained in experiments on Cambridge deaf children (Yudkin, 1943). It is probable that the lack of effect of supplements of vitamin C in the oft-quoted experiment on South African miners (Fox *et al.*, 1940) was due to the simultaneous existence of multiple deficiency; restoration of an adequate supply of this one substance without increasing the supply of the other nutrients was itself not sufficient to affect the health of the workers, apart from decreasing the number of cases of frank scurvy.

Lastly, when a positive effect is obtained by the use of a vitamin supplement it is not always legitimate to assume that this has proved the existence of deficiency. The fact that vitamin C is diuretic and ceases to relieve the oedema of cardiac failure (Evans, 1938) does not of course imply that the condition is due to deficiency of the vitamin. In fact, as has been suggested, large doses of vitamin D have a curable effect on psoriasis (Bruns, 1938) it is not to be regarded that psoriasis is a deficiency disease. It is important, in other words, to distinguish between replacement therapy and pharmacological therapy.

#### General Comments

Diagnosis by rule of thumb, without consideration of biological realities, is to be deprecated no less with deficiency disease than it is with any other condition. We may mention a few of the more important considerations which must be borne in mind.

**Multiple Deficiency.**—Human diets are such that deficiency of one nutrient only is unlikely to occur. This means that Criterion 1 may indicate deficiency of a nutritive factor which is not the cause of the condition under investigation. It would appear that the signs which will occur in a multiple deficiency will depend partly on the relative extent of the various deficiencies and partly on the capacity of the organism to store the different dietary factors. On a diet completely deficient in the vitamin B complex, for example, rats will not certainly die of deficiency of vitamin B<sub>1</sub>, before developing signs of other deficiencies.

**Individual Variation in Requirement.**—It cannot be expected that all individuals have exactly the same requirements for the various nutritional components or that they would show the same signs when depleted of one or more of these components. It is possible that there are also racial as well as individual differences, as illustrated by the reported behaviour of

Rumanian and Russian prisoners in a German camp during the last war. It is stated (Bigwood, 1942) that all were on the same diet, yet the former developed pellagra and the latter scurvy.

**Other Constituents of the Diet.**—It has been shown that signs of deficiency of riboflavin can be considerably aggravated if the deficient subjects are dosed with other components of the B complex (Sebrell and Butler, 1938; Sydenstricker *et al.*, 1940), and there is similar experimental evidence in dogs (Morgan, 1941). This provides another reason for considering the whole of the diet in attempting the diagnosis of deficiency disease.

**Specificity of Tests for Deficiency.**—No single test can be held to prove deficiency. There are, for example, other causes of poor dark-adaptation than deficiency of vitamin A; other factors producing increased capillary fragility than deficiency of vitamin C. It is possible also to have a high level of vitamin A in the blood coexisting with definite functional deficiency of this vitamin.

Finally, it should be stressed that, even if deficiency has been proved, it may be the effect rather than the cause of the condition. An extreme example is deficiency of vitamin C in tuberculosis, in which it is clear that no one would suppose that the deficiency causes the infection. On the other hand, it should be remembered that, even when it is not the ultimate cause of a definite pathological state, deficiency may be a predisposing cause. It is likely, for example, that deficiency of either vitamin C or nicotinic acid renders the individual more readily susceptible to ulcerative stomatitis.

I am greatly indebted to my brother, Flight Lieut. Simon Yudkin, for much helpful discussion and criticism during the preparation of this paper. To Dr Leslie Harris I owe the encouragement and stimulus which aroused and maintained my interest in nutritional problems.

A. V. Hardy (*Publ. Hlth. Rep.*, Wash., 1943, 58, 833) used sulphadiazine in the treatment of 19 chronic typhoid carriers, 4 convalescent carriers (including one treated as a case), 21 clinical cases, and 1 clinical relapse, with the following results. Quantitative cultural tests showed that sulphadiazine had a marked bacteriostatic effect on *Eberthella typhosa* in the enteric tract, but that the chronic carrier state was not terminated by this treatment.

## THE PRISONER-OF-WAR MENTALITY ITS EFFECT AFTER REPATRIATION

BY

P. H. NEWMAN, D.S.O., M.C., F.R.C.S.

Major, R.A.M.C.

In 1919 Dr. A. L. Vischer wrote a small book entitled *Barbed-Wire Disease: A Psychological Study of the Prisoner of War*. It deals briefly with the factors producing this "disease" and with the prisoner's reaction to his environment during prison life. Dr. Vischer was a visiting doctor in German prisoner-of-war camps during the last war; he drew his conclusions not as a prisoner of war but as a psychologist studying a series of patients. His experience was vast, and his conclusions were drawn from an immense amount of data. In this short article I wish to give an impression not of a doctor examining his patients but that of a prisoner of war himself.

The number of prisoners ultimately returning to this country alone will be many hundreds of thousands, and that to countries throughout the world millions. It is quite obvious, therefore, that the organization dealing with repatriation of these people constitutes one of our more important post-war problems. The return of these prisoners will entail a flooding of our own country with men and some women who have experienced circumstances not necessarily harder but quite different from the majority of others. Those at home will welcome them as few are privileged to be welcomed, not because they have lived through worse conditions or have been more badly wounded or mutilated or have shown greater courage in facing more frightful scenes than others, but because they have lived in the valley of darkness.

During this period of enforced imprisonment they have adopted a certain mental attitude—a frame of mind compatible with camp life. Dr. Vischer has traced most carefully the origin of this mental attitude and discussed in detail its symptoms during camp life; he has not, however, described the symptoms after release from the camp. It is perfectly easy to understand the reason for a prisoner's depression while confined in a small space, crowded, and in an atmosphere of irritability. It is far less understandable that this attitude should persist on the prisoner's return to conditions to which he was normally accustomed. Broadly speaking, a prisoner's reactions in the camp are of minor importance in comparison with those which he shows on return to his normal life when he may again be beset by large responsibilities.

In medical textbooks we are familiar with what is called caisson disease. While in an underwater or compressed-air caisson such as is used in tunnelling, the bodies of the workers adapt themselves to an environment in which the atmospheric pressure is abnormally high. While working in this situation men show no abnormal symptoms, but when the caisson is raised or when they are released from it, the pressure falls back to normal and symptoms are apt to appear as a result of liberation of nitrogen bubbles from the blood. These symptoms do not always occur, but are usually the result of a too rapid fall in atmospheric pressure—that is, on a change of environment which the body finds too rapid for proper adaptation.

When a number of men are released from the same caisson, all of whom have been submitted to the same atmospheric pressure, some will show symptoms and some will not. A batch of men exposed to a high pressure for a long period will be more likely to show symptoms than a batch exposed to a low pressure for a short period. It is apparent, therefore, that the presence or intensity of these symptoms will mainly depend upon the following factors: (1) the individual himself; (2) the length of the period of immersion; (3) the pressure within the caisson. This response of a normal body to the process of recovery from exposure to an abnormal external environment is wrongly called a disease. It is the change-over from an adaptation to abnormal external influences. The

returned prisoner of war is placed in conditions which are some parallel to those who suffer from caisson disease.

If we bear this parallel in mind we may say that in repatriated prisoner the appearance of symptoms will depend upon: (1) the individual temperament; (2) the period of time within the camp; and (3) the gravity of conditions. (By gravity of conditions is meant not necessarily the degree of physical discomfort and the occurrence of atrocities, but the intensity of factors which the prisoner feels are of psychological importance.)

The effects of internment are twofold, and can crudely be divided into physical and mental. The physical effects are easily described and easily accounted for. Their treatment after release is probably a matter of good food, elementary medicine, and pleasant conditions. It is not the object of this article to discuss these problems, which are already recognized and can usually be treated without difficulty. The possibilities and limitations of physical rehabilitation are common knowledge among the medical profession. Unfortunately this is not the case in mental convalescence, where, as doctors, we still tend to flounder in directing treatment. Formerly, what we call common sense was the guiding principle and it will remain so unless some very clear and rational indication for additional methods arises. The use of individual psychological treatment for any returned prisoner of war seems to be debatable; it may carry with it a public acknowledgment of mental abnormality, which must at all costs be avoided. This will be discussed more fully later when the long-distance guidance of such cases is discussed.

Barbed-wire disease, as has been said, is a misnomer, wrongly called a disease, and perhaps is better termed a mental attitude. This mental attitude is built up from a series of four phases through which the average internee passes. They are quite definite in occurrence but nebulous as to length and intensity. The officer prisoner of war has been chosen for discussion for two obvious reasons—first, the contrast between his normal life and his prison life is greater; and, second, during internment he remains unemployed and therefore has to rely on his own resources to dispose of his time.

### Stage I: The Breaking-in Period

This is by far the most unpleasant of the four stages because it is essentially the time of the acute mental strain which accompanies forcible adaptation to a lower plane of existence. The captive realizes very quickly the loss of friendship, association, the loss of his own reputation and prestige, the absence of the sunshine of his own propaganda, and the power of the opposing propaganda. The lot of the man who was taken prisoner in France after three weeks of exhaustive retreat may well serve as an example. Within a month he was switched from the pleasant life of a pseudo-peace-time Army into the grip of Nazi persecution. Bewildered by the falsity of his own propaganda and disillusioned as to the might of his own country, hungry and fatigued to the extreme, he was moved into Germany. He was taken in by forced marches, given practically nothing to eat, and shot if he fell by the wayside. Lack of clothes, lack of personal belongings, and, above all, the vision of five to ten years as a prisoner of war were some of the factors which combined to make the prisoner a truly wretched creature. During this period there first arose the longing for freedom, for home, security, female society, and, above all, for sympathy. This suppressed longing for sympathy remains, and is stored up until the day of repatriation, when it crops up in different ways.

### Stage II: Period of Convalescence

This is the period of recovering morale. The prisoner, having reached the depth of his depression, gradually reawakes to the life around him. He licks himself and his wounded pride, opens his eyes, and finds that far away on the horizon there is still a ray of sunlight left. Now he begins to shake and to undress when going to bed, to talk intelligently, to plan and to organize his life. He grasps at the small things which give him pleasure and builds his life around them. At this time, typically, he gathers together what little personal belongings remain to him. He searches the camp for a piece of wood and fixes it to the wall near the head of his bed.

On this shelf he sets a photograph, a pipe, a favourite book, anything else which represents to him a home in miniature. During the period of increasing morale the prisoner develops a sense of revenge, and is not long in realizing that revenge is impracticable. The consequent sense of frustration may easily be turned into a grudge against his own Government and higher Service officials. During this period of recovery there is possibility of a reason or an object for living gradually emerges and forms itself from the all-enveloping fog of altered values. Some find this image more quickly and realize it more clearly than others. They are the fortunate ones who adapt themselves more readily to prison life. Others, to find the definition of this image more difficult, remain restless, discontented, more indefinite in their prison day routine, and are liable to store up from frustrated revenge a heavy grudge against the future if it does not come up to expectations. Let it not be forgotten that many prisoners of war have not seen a friendly person outside the barbed wire for over three years. This lack of external friendliness and encouragement plays a large part in focusing the prisoner's thoughts and ideas in introspective channels.

### Stage III: The Lengthy Period of Boredom

During this period we see the prisoner in his usual state. He has done his best to accommodate himself to a life in a nutshell. He has looked into the uncertainty of the future and weighed up the possibilities of his eventual home-coming.

Dr. Vischer has pointed out, this uncertainty of the duration of imprisonment is a demoralizing factor. The criminal prisoner can plan his life to the duration of his imprisonment, the prisoner of war cannot.

The significance of the absence of female society as a factor in the formation of the prisoner's attitude appears to give rise to much controversy. In discussing sexual deprivation it is important to distinguish between the restricted meaning of this phrase—i.e., actual sexual intercourse—and the broader meaning—i.e., the whole sphere of association between the sexes and all that it entails. There can be little doubt that, in a broader sense of lack of affection, sexual deprivation is not only a fundamental but the fundamental factor in the formation of the prisoner-of-war attitude. Deeply within the prisoner, but seldom expressed, there lies the fear of becoming an forgotten man. In 1941, after a year or so of imprisonment, some two hundred and fifty officers were gathered together to listen to a newly arrived Air Force prisoner. He was giving a recapitulation of the events in England since Dunkirk. Interesting his talk was, nothing stirred the audience so much as when he concluded by saying, "And, chaps—the girls still love you." This acute emotional reaction after this was plainly obvious. The proof of this need can be seen in the meticulous care with which every word of letters is read and sifted. Hours are spent in making an elaborate checking and filing system of incoming and outgoing mail, and statistics are kept of its value.

The importance of the absence of actual sexual intercourse probably depends a great deal on the temperament of the individual. Even although it is untrue, it is quite common among Italian prisoners of war to believe that he will become sexually deranged without this physiological act. I have heard this view expressed also by French prisoners, but never by British or German prisoners of war. A quite unfounded fear of impotence was frequently the reason for a prisoner's seeking medical advice and reassurance.

Overcrowding, with the impossibility of ever being alone for work, was a source of irritation and a good excuse for idleness at all.

Part from all these demoralizing influences there are several aspects of this life which produce other but equally damaging effects. In the camp the prisoner is relieved from the struggle for life; he no longer has to work for his living, shoulder responsibility, or worry financially. Nothing that he does in the camp can relieve any threatening situation at home, therefore his occupations lose their significance as actual vital importance and become merely a pastime to amuse himself and defeat his own boredom. There is no stimulation in him to work, and what he achieves matters very little to his present state. He may spend three months making a model

boat, and if he wishes he can spend six, for nobody will interfere; there is no competitive element, and time is of no importance. This attitude and this lack of responsibility tend to make him small-minded and childish. Conversation centres around small events within the sphere of the camp, events which are of no consequence to the outside world. This lack of stimulation builds up a predisposition to be unduly troubled by the everyday struggle for existence which has to be met, once again, after release.

The unemployed prisoner of war has three main ways in which he may lead a constructive life, the choice varying according to his temperament: (i) work which will be of value to him after release; (ii) welfare work among his fellow-prisoners; (iii) escaping and sabotage. Most prisoners mould their occupation around one or more of these three. The minority which does not adopt any one of these seriously is building up greater difficulties at the time of readjustment following release.

### Stage IV: The Repatriation Period

The returning prisoner arrives back in his home country keyed up to a high pitch and full of expectation for the pleasures to come. He is stimulated, after years of looking from the other side of the river, into a state of exaggerated optimism and false hope. Much, for the future, will depend upon the state of his home conditions. The repatriate who finds his family and his intimates as he hoped to find them, ready to listen sympathetically and to share his experiences, however trifling they may have been, is already half-way on the road to recovery. He must regain his emotional balance before he can again assume the responsibilities of his former life. Here in the bosom of his family he may live quietly, and gradually catch up with the years that have been lost to him. Here are those who have lived these years for him and are willing to share their experiences and help him over the gap of wasted time. From this sound emotional foundation of his convalescence he will stand every chance of regaining his normal appreciation of the difference between work and relaxation and of his need for both in certain proportions. Greater difficulties are apt to beset the returned prisoner who is not so fortunate. In wartime many factors tend to upset the happy balance of affairs, and consequently grave gaps and differences are apt to appear. During this repatriation period abnormal reactions are common; in fact, probably all prisoners of long standing will present symptoms to some degree. The factors on which the occurrence of symptoms will depend are those described above, with the addition of the conditions awaiting the prisoner on return home. Briefly, these symptoms are restlessness, irritability, disrespect for discipline and authority, irresponsibility, and even dishonesty. Other symptoms that occur are the fear of enclosed spaces, especially a fear of large crowds in confined spaces, cynicism, embarrassment in society, rebellious views against any code which tends to restrict the repatriate's activities, and a tendency to quick and violent tempers.

All men returning from overseas, and especially those who have been in isolated areas for long periods, will show these symptoms to a certain extent, but seldom to so marked a degree as in the prisoner of war who has been through conditions which are usually held to be more damaging in the psychological sense: this, too, the prisoner knows and feels. It is important that the returned prisoner of war who shows these symptoms shall not be regarded as abnormal. Some may think him peculiar, rude, objectionable, and unreliable; but they must be helped to realize that he is a normal person attempting to bridge a gap in his life, often with poor or insufficient material.

This syndrome, when it exists, should pass off after six months to one year, and thus those affected should give rise to no concern. There are two types, however, which will give cause for anxiety: (i) the repatriate with exaggerated symptoms, (ii) the repatriate with persistence of symptoms. If individual treatment of any sort is ever indicated it will be in one of these two types. The first type is associated with symptoms of severe restlessness, irritability, emotional outbursts, acute discontent, and possibly excessive alcoholism. The second type shows chronic apathy, loss of initiative, and loss of

12 JAN. 1, 1944

*Technique.*—The routine adopted for patients with previously normal or only slightly irregular menstrual histories consisted of one intramuscular injection of 1 mg. of prostigmin on three successive days, this treatment being discontinued if after the first or second injection the menstrual flow was restored. With the exception of two cases which failed to respond, the longest interval between the last injection and the onset of menstruation was about 72 hours. These periods were normal in quantity and duration, and in two cases biopsy proved the flow to be of a truly menstrual character.

Table of Results	Bleeding Occurred

2	..	..	10	
3	..	..		
	Control	..		

Group 1: Pregnant patients.  
 Group 2: Poorly selected cases; 4-mg. doses of prostigmin injected, only occasionally 1 mg.  
 Group 3: Properly selected cases; 1-mg. doses given from the beginning.  
 Controls: Out of Groups 2 and 3; sterile water injected.

A 2-para. Has always had regular periods and April with a delay of three weeks. After prostigmin. After one test.

Group 1: Pregnant patients.  
Group 2: Poorly selected cases; 1-mg. doses of prostigmin occasionally 1 mg.  
Group 3: Properly selected cases; 1-mg. doses given from the beginning. Out of Groups 2 and 3; sterile water injected.

**Illustrative Case.**—A 2-para. Has always had regular periods, and presented herself in March and April with a delay of three days each time. She was treated with prostigmin. After one injection of 1 mg. on each occasion a normal period started. In August she had a delay of 8 days. Two full courses of prostigmin at an interval of 8 days had no effect. An A.-Z. test was returned positive, and later the pregnancy was confirmed clinically.

**Complications**

A number of patients complained of frequency of micturition and giddiness. One woman with a menstrual delay of 8 days complained, 20 minutes after the second injection of 1 mg., of "a film before my eyes, strong palpitations, sickness, and a terrific rush of water which came out of my mouth." She rapidly recovered from the attack without treatment. The action of prostigmin on the salivary secretion may conceivably have been the cause of some of these symptoms (Wright, 1940). This was the only really unpleasant incident in the series.

**Conclusions**

The patient and the length of the treatment are the factors determining the cases.

**Conclusions**

It appears that the age of the patient and the length of the menstrual delay are not decisive points in selecting the cases; some observers have reported successful treatment in patients with a delay up to 52 days. The character of the previous menstrual cycle, which should have been quite regular or have shown only slight variations, is of greater importance. Prostin is reliable in its action, as is shown by its success in 94.5% of this series. One wonders whether the two failures may not have responded to a fourth injection or to slightly larger doses. The drug causes some minor discomfort of a transient and not serious character, but it is quite safe and pregnancy is not disturbed.

The type of patient we had to deal with raises the question whether a wait-and-see policy or any other "psychological treatment" may not have been followed by similar success in a considerable percentage of cases. The injection of sterile water in 10 cases, previous to the proper prostigmin course, gave entirely negative results. Even if it were true that in cases of "functional amenorrhoea" the period will appear sooner or later with rest, tonics, etc., it should be borne in mind that prolonged amenorrhoea may lead to atrophic changes in the uterine muscle. The results are encouraging, and prostigmin deserves further clinical trial. We would suggest that the drug should be tried in all cases of delayed period except those of endocrine origin and those in which pregnancy has been established. Further clinical work may also reveal interesting effects of prostigmin in cases of dysmenorrhoea.

Summary

**Summary**

Ninety cases of amenorrhoea were treated with prostigmin. From 1 to 3 injections of 1 mg. were given.

The results obtained were favourable: in 94.5% of the cases of delayed period not due to pregnancy the menstrual flow was restored.

Prostigmin is safe; from its use no serious ill effects were observed. There is no tendency of the drug to interfere with the course of pregnancy.

A Case of Dysentery associated with  
*Bact. alcalescens*

**A Case of Dysentery**  
**Bact. alcalescens**

The following case may be considered of interest seeing that only in the last few years has *Bact. alcalescens* been recognized as an organism capable of producing acute dysentery. Nabar and Edward's (1939) paper on this subject has induced us to regard the case as worthy of record.

CASE RECORD

On 25. was admitted to hospital with diarrhoea for six weeks.

CASE RECORD

Mrs. M., a nursing sister aged 25, was admitted to hospital on Sept. 9, 1941, with a history of intermittent diarrhoea for six weeks. After admission her stools presented typical dysenteriform appearances, and she was given appropriate medicinal and dietetic treatment. At no time was she acutely ill, nor did she have much pain. Under treatment she improved, but blood and mucus in stool amounts persisted in the stools for some weeks. On Sept. 9 a stool, submitted before admission, consisted of gross blood-clot with out visible faecal matter; it was cultured on two Wilson and Blair plates and tetrathionate broth (paratyphoid infection was suspected also on two MacConkey plates. The Wilson and Blair plates were covered to be entirely negative. Both MacConkey with a few colonies to a profuse growth of non-lactose-fermenting organism was identified as *B. coli*. The non-lactose-fermenting organism was identified from its cultural and fermentative reactions by the E.M.S. Laboratories as *Bact. alcalescens*, but was not agglutinated by either of the sera available for this organism in the National Collection. Stools examined on Sept. 23 and Oct. 10 and 18 all contained small quantities of blood-stained mucus, and all, on culture on MacConkey plates, gave a heavily preponderant growth of *Bact. alcalescens*. Serum only a few colonies of *B. coli* and *B. lactis aerogenes*. The paratyphoid group. Serum obtained on Oct. 13 showed no agglutinins for the patient's own strain of *Bact. alcalescens*. This was confirmed by the E.M.S. laboratories, which also tested for agglutinins for all the available strains of dysentery bacilli, with a negative result.

On Nov. 4 a live broth culture of *B. acidophilus* was administered for a fortnight. A stool examined on Nov. 8 contained a negative result to tests for *B. coli* and *B. lactis aerogenes*, but a few colonies of *B. acidophilus* were present.

From Nov. 4 a live broth culture of *B. acidophilus* was administered daily for a fortnight. A stool examined on Nov. 8 contained no blood or mucus, and gave a negative result to tests for occult blood, and on culture showed only *B. coli* and *B. lactis aerogen*. A stool examined on Nov. 21 contained no blood or mucus, but a small number of *Bact. alcalescens* were found, with numerous *B. coli*. As the patient was now free from all symptoms she was discharged from hospital.

It has been suggested that the absence of agglutinins is again the causation of dysentery by *Bact. alcalescens* in this case. I find this hard to believe in view of its presence in overwhelming numbers and the complete failure to discover any other cause in spite of repeated examinations.

The apparent clearing up of the remaining symptoms after the administration of *B. acidophilus* culture is suggestive, might, we think, be of use in other similar cases.

A Case of Cystic Hygroma

The following case may be considered a warrant publication.

Early in Sept., 1942, a child aged 20 months was brought to me by her mother, who had noticed a swelling in the left side of neck, gradually becoming more apparent since birth. I found a rounded swelling above the outer half of the left clavicle, diagnosed a lipoma. I advised leaving it alone unless it showed signs of growing or caused pain. About a year later she was brought back to me with the complaint that the swelling was growing. It was apparent on examination. The child was admitted to H. and Wexlstone Hospital, and on Sept. 25, 1943, under general anesthesia, a large cystic tumour was dissected out apparently completely.

extended from one and a half inches below and behind the clavicle to a point near the middle line of the neck behind and up to the trapezius, and was also adherent to the posterior border of the sternomastoid. The cyst was multiloculated and contained straw-coloured fluid. The pathological report from the Middlesex Hospital laboratory was: "The mass consists of oedematous connective tissue with varying-sized spaces lined by a very thin layer of endothelial cells. A fair number of blood vessels are present, but no blood spaces. The picture is that of a cystic hygroma." The wound was drained for 48 hours owing to the size of the abscess, and healed without any apparent discomfort to the child.

HAROLD E. THORN, M.B., B.S.

## Thrombocytopenic Purpura following N.A.B. Injections

This is a case of thrombocytopenic purpura following N.A.B. injections in a congenital syphilite. It is placed on record because of the severity and acuteness of the symptoms and extreme reduction in the platelet count.

### CASE HISTORY

The patient, a soldier aged 30, was admitted on April 20, 1943, his complaint was bleeding from the gums for three days, bruising of the limbs, and petechiae all over the body for two days. He gave a history of having been treated with bismuth and arsenic for the past eighteen months for syphilis. The bleeding from his gums started about four hours after his last arsenic injection. He had no previous history of bleeding.

On examination the patient was seen to be a well-nourished man with a good colour. No clinical evidence of anaemia was present. There were petechial haemorrhages all over his body, large bruises on his limbs, and a slight oozing of blood from his gums. The spleen was not palpable. No abnormality was detected in heart or lungs. His pupils were equal, central, and circular, and reacted to light and accommodation. Knee- and ankle-jerks were absent and plantar responses were flexor on both sides. There were no sensory changes. His blood count on admission was: R.B.C., 4,130,000; Hb., 5.800; Hb., 78%; C.I., 0.95. The differential white cell count was normal. Platelets numbered 4,130 per c.mm. The red cells showed anisocytosis, with many crenated forms. There were no nucleated red cells. Clotting time was 64 minutes (normal 4 minutes) (capillary method used). Bleeding time was 14 minutes (normal 3 to 6 minutes).

On April 22 the patient complained of acute pain in the right costo-vertebral angle extending down to the groin, and passed blood-stained urine. He was given vitamin P, ascorbic acid, sodium dihydrophosphate intravenously, and massive doses of potassium citrate. In the 23rd the bleeding from the gums and the haematuria increased. During the day one pint of Group O (IV) blood was transfused as a slow drip. There was a slight improvement in the patient's condition after this, and the bleeding from the gums became much less. His blood count was now: R.B.C., 4,020,000; Hb., 11,700; Hb., 76%; C.I., 0.95. Platelets had fallen to 3,000 per c.mm. On the 24th it was noticed that there was a rather diffuse swelling just beneath his mandible. He was given two pints of whole blood by slow drip (54 hours). He improved a little after this, and the bleeding from the gums almost stopped. On April 25 his gums started to bleed again and he had haematuria. He was given 1 c.cm. of colloidal calcium every six hours and 2 c.cm. of ahaematin intramuscularly. That night he seemed very much improved, but in the early hours of the 26th he suddenly died.

At necropsy the findings were as follows: "There were numerous petechiae all over the body. There was also slight jaundice. The lungs were oedematous and the trachea was filled with blood-stained sputum. There was a recent pleurisy. The external surface of the heart was covered with petechiae. There were large haemorrhages to the mesentery. The liver (1,475 g.) was congested, and there were numerous petechiae on its surface. The kidneys were congested and the pelvis filled with blood-clot. The spleen (250 g.) was soft." The bone marrow was, unfortunately, not examined.

### DISCUSSION

In 1930 Bamforth and Elkington recorded four similar cases following N.A.B. and other antisyphilitic preparations. They found only 19 cases in the literature, and 10 of these were fatal, treatment with blood transfusion and liver extract having no effect. Scarborough and Stewart (1938) and Scarborough and Horne (1940) showed the value of vitamin P (hesperidin) in the treatment of purpura occurring as a toxic manifestation of arsenic and bismuth in the treatment of syphilis.

In the present case vitamin P and all treatment proved of no avail. Blood transfusions caused only temporary improvement in the condition.

I am indebted to Dr. T. J. Hennelly, medical superintendent, for permission to publish this case, and to Dr. J. M. Naftalin for carrying out necropsy and laboratory investigations.

## Reviews

### TECHNIQUE OF BLOOD GROUPING

*Blood Grouping Technique: A Manual for Clinicians, Serologists, Anthropologists, and Students of Legal and Military Medicine.* By Fritz Schiff, M.D., and William C. Boyd, Ph.D. With foreword by Karl Landsteiner. (Pp. 248. 55.00) New York: Interscience Publishers Inc. 1942.

Schiff's contributions to our knowledge of blood groups were numerous and important, and ten to fifteen years ago his book *Die Technik der Blutgruppenuntersuchung* was of great use. Before his untimely death Schiff had been for some years in America, and there he sought the help of W. C. Boyd, another well-known worker in the field, in the preparation of an up-to-date account of blood grouping somewhat on the lines of his German book. The plan of the book was Schiff's, and it was more than half finished when he died. From such a source a modern work was bound to be important, and *Blood Grouping Technique: A Manual for Clinicians, Serologists, Anthropologists, and Students of Legal and Military Medicine* is packed with information. It is essentially a book in which to look up points, and the arrangement of the matter in short sections numbered on a decimal system greatly helps reference and cross-reference.

Experienced workers will disagree with many things in it, and beginners will probably be confounded by the elaboration of the complexities and pitfalls. Blood grouping is far from being a simple business, and knowledge of the difficulties is essential for success; but in reading the book the reviewer has several times been struck by a sense of unreality in parts of the subject-matter, and has wondered whether some of it has been written by a theoretical rather than a practical blood grouper. From a lengthy list of things that might be criticized, queried, or contradicted, a few may be mentioned. On page 27 it is recommended that before use the efficiency of anti-A sera for A<sub>2</sub> cells should be tested; no mention is made of testing against A<sub>2</sub>B cells in which the A may be very much weaker than in A<sub>1</sub>. There is little danger of anti-A serum worth anything at all missing A<sub>2</sub> cells, the danger is with A<sub>2</sub>B. Perhaps it is only inadvertently that it is suggested near the bottom of page 38 that 50% of group AB are A<sub>2</sub>B. Actually the proportion of A<sub>2</sub> is the same in A and AB—about one in four or five in this country and the U.S.A. The advice on page 42 to use a technique which fails to disclose weak irregular reactions is very bad; this is the way to miss weak A in the AB group. On page 57, "Sometimes more practice and skill are needed for these [MN] tests than for routine blood grouping..." is an amazing understatement. Accurate MN work needs very great experience. The statement on page 58 that transfusion of blood of one group into a patient of a different group is "often" successful where the donor's cells do not meet homologous antibodies in the recipient's serum misrepresents the situation; "often" should be omitted.

The book is not merely a manual on technique; there are sections on transfusion, blood donor services, blood substitutes, the Rh factor, medico-legal grouping, anthropology, and, in fact, on everything found in other textbooks on blood grouping. Perhaps the subject is too big nowadays for really adequate treatment by one or even two authors. In the sections on transfusion, donors, and blood substitutes practically no mention is made of what has gone on in this country since the war began. Yet in spite of its defects the book will be very useful, and the reviewer intends to keep a copy handy in the laboratory.

### INSECTS OF MEDICAL IMPORTANCE

*A Handbook for the Identification of Insects of Medical Importance.* By John Smart, Ph.D. With chapters on Fleas by Dr. Karl Jordan, F.R.S., and on Arachnids by R. J. Whittick, B.Sc. British Museum (Natural History). (Pp. 269; illustrated. 15s.) London: Printed by Order of the Trustees of the British Museum. 1943.

Identification of a pest insect is to an entomologist what diagnosis is to a doctor. In this country it is possible to have one's conclusions checked by a museum expert within a short time. But many entomologists and medical men are confronted with noxious insects and insect-borne diseases in the remoter parts of the world where they depend on their own powers

of identification. On such occasions the readily workable keys provided by this book will be of inestimable value.

The scope of the book is strictly defined by its title: for its 269 pages are allocated, to a large extent, according to the difficulty of identification and the medical importance of the various groups. One hundred pages are accorded to mosquitoes and 75 to the remainder of the diptera, while other insects (except the fleas) claim only 10. It is possible that Dr. Smart's intimate knowledge of and interest in the diptera have slightly exaggerated their importance as compared with other groups. Thus, the Reduviid bugs might claim equal attention to the Tabanid flies; but whereas the latter receive four pages, the Reduviids are dismissed in one short paragraph. However, it must be admitted that most of the medically important insects are indeed found among the diptera, and the book is well worth purchasing for the keys to this group alone. Dr. Jordan provides a welcome key to the important genera of fleas, with notes on many of them; and Mr. Whittick has added a useful section on Arachnids. The illustrations are admirable and the price, under present conditions, is extremely low.

### THE MALE SEX GLANDS

*The Sexual Glands of the Male.* By Oswald S. Lowsley, M.D., F.A.C.S. Oxford Medical Publications. (Pp. 746; illustrated, 55s.) London: Oxford University Press, 1943.

In this book the work of several contributors to the *Oxford Loose-Leaf Urology* has been assembled and reprinted to form a single volume. Dr. Lowsley, the well-known authority on the prostate, has dealt with the embryology, anatomy, pathology, and surgery of that organ. His description of the surgery of the malignant prostate includes the more recent method of treatment with oestrogen and castration, but he is of the opinion that this does not obviate the necessity for radical operation whenever this is possible. In such cases he recommends the perineal approach. Drs. Hinman and D. R. Smith are responsible for those sections of the book dealing with the testicle and epididymis, and Dr. Gutierrez for the articles on the vas and the seminal vesicles.

The work is profusely illustrated and the general lay-out is excellent. It is primarily a book for surgeons, and if any criticism is to be raised it is that the non-surgical treatment of genito-urinary lesions has been less adequately dealt with than the surgical. The treatment of infertility by hormone therapy and the treatment of impotence by psychotherapy are scarcely mentioned, and there can be no doubt that they are of considerably more importance than any surgical measures. There are few authorities on male sexual disabilities who would agree with the authors that pathological lesions of the genital tract are to be found in the majority of impotent men. But *The Sexual Glands of the Male* is a book written by surgeons for surgeons, and it is not surprising therefore that the medical and psychological aspects of these important subjects are not adequately dealt with.

### Notes on Books

A fourth edition has now appeared of Dr. W. WILSON INGRAM's useful book *The Diagnosis and Treatment of Diabetes* (Sydney and London: Angus and Robertson, Ltd.; 6s. 6d.). In revising his text the author has added new matter at various places, and in particular the chapter on the complications of diabetes; but, to keep the volume approximately the same size (150 pages), he has deleted the chapter on the estimation of glucose in blood. This is essentially a book for general practitioners, many of whom have already found it a helpful guide, with clear-cut directions, especially on diets.

A 14th edition of Mr. H. WIPPELL GADD's *Synopsis of the British Pharmacopoeia* has been published at 3s. 6d. by Baillière, Tindall and Cox. This edition comprises the six Addenda to the B.P. which have been issued since the main work was published in 1932. This additional matter will prove very useful to those seeking a brief summary of the changes contained in the official Addenda. The section on the Poisons Laws has been revised in accordance with latest Orders.

The *Calendar of the Royal College of Surgeons of England* for 1943 is published by Taylor and Francis Ltd., Red Lion Court, Fleet Street, at 2s. 6d. It has suffered a still further diminution in size owing to the shortage of paper, but all the essential official information is given and the Register of Fellows in alphabetical order appears in its accustomed place.

## Preparations and Appliances

### INSTRUMENT FOR MANIPULATION OF CENTRAL MIDDLE THIRD FRACTURES OF FACE

Mr. ARCHIBALD H. MCINDOE, F.R.C.S., F.A.C.S., writes from a Plastic Surgery and Jaw Injuries Centre:

Impacted central middle third facial fractures with retro-position of the alveolar segment require forcible disimpaction and advancement in order to obtain good dental occlusion. In carrying out this manipulation a strong grip of the alveolus is necessary, using an instrument which will do a minimum of damage to the buccal mucosa and none at all to the incisor

teeth. I have designed the forceps illustrated herewith for this purpose. The jaws are broad and strong and do not shut completely. Each is shaped to the area to be gripped and fitted with fine pin-teeth so that the alveolar bone above the incisor teeth can be firmly held but not crushed during the movement necessary for reduction. In practice they have proved most satisfactory for this purpose.

The forceps are manufactured by Messrs. Thackrays, Ltd

### RESUSCITATION BY ROCKING

Dr. W. F. CORFIELD, Medical Officer of Health for Colchester, writes:

You have recently published a number of suggestions for apparatus for rocking stretchers for Eve's method of resuscitation. In my opinion, none of them is as handy or complete as the apparatus suggested by Mr. A. V. Gooch, the Civil Defence Staff Officer for the casualty services of Colchester. This apparatus, as the illustration shows, consists of a bar which will fit on to a trestle, two chair backs, the edge of a table turned on to its side, or anything of this sort. Supported on the bar are two uprights, which will swing upon the bar when a civil defence stretcher has been placed in the slots upon them.

An important improvement of this apparatus is the addition of a block of hard wood hinged upon each upright with a channel fixed upon it into which the Army (Furley) stretcher can be fitted. This block can be tilted down out of the way when the C.D. stretcher is in use, or, if a Furley stretcher only is available, the block can be tilted up above the grooves of the C.D. stretcher and the channels on the blocks take the place of the grooves and receive the poles of the Furley stretcher. The apparatus is found to be most satisfactory with both types of stretcher.

The advantages are that it is handy (weight 7 lb.), can be immediately brought into action, is cheap to make, the cost being about 15s., and the whole apparatus is easily kept upon a shelf without taking up much room.

# Shadows that speak

A clear-cut shadow on the X-ray plate is an asset of no mean value in diagnosis. Internal contrast agents of proved dependability, such as those listed, ensure consistently satisfactory results.

# EPIDEMIC INFLUENZA VIRUS SUSPENSION

## I. V. S. (B. D. H.)

*For the prevention of epidemic influenza*

Now is the time generally considered to be most suitable for immunising patients against epidemic influenza, the recent mild outbreak of which may recur with greater virulence in January and February. Subcutaneous injections of 1 c.c. of I.V.S. (B.D.H.) have been found effective in producing active immunity towards epidemic influenza which lasts for approximately twelve months. A short interval elapses between the injection and the development of maximum immunity; resistance to infection therefore reaches its height at the time of the expected recurrence of the disease.

It must be emphasised that I.V.S. (B.D.H.) protects against true epidemic influenza; it is not effective against those infections (usually febrile catarrhs) with protean symptomatology which are commonly called influenza.

## THE PLACE OF CONSCIOUSNESS

As the artist stands back from his work from time to time and contemplates it before proceeding to a further stage in its completion, so in the field of scientific observation it is necessary to pause now and again to contemplate the facts of observation already accumulated, and to see what general ideas may be drawn from them. There is an intellectual refreshment in this contemplation, and in what may be called the escape from an exclusive preoccupation with the mass of detail into the realms of general thinking; but there is more in it than this, for it is an essential step in any ordered quest for fresh knowledge. In this mood Prof. Geoffrey Jefferson, in his address before the American Neurological Association on the nature of concussion, which appears at the opening pages of this week's *Journal*, has thoughtfully reviewed the field of clinical and pathological data at our disposal, and has formulated some general ideas therefrom. In doing so, not only has he given his readers the refreshment they have learned to expect from his writings, but he has provided a welcome example of the order of general thinking of which we stand in so great need in medicine to-day.

The phenomena of concussion have found their latest description and analysis in the experimental work of Denny-Brown and Ritchie Russell. They include loss of consciousness, alterations in the depth and frequency of respiration, in the pulse rate and the blood pressure, and also in certain lower-level somatic reflex reactions (laryngeal, pharyngeal, corneal, and of deglutition): a symptom-complex which corresponds to that found in man by clinical observation. Of the component elements, all but the first, as Jefferson points out, may now be confidently attributed to a paralytic effect on neurons, including especially those of the hypothalamus and brain-stem. Changes in the vascular supply of the cerebral hemispheres may now be regarded as epiphenomena of secondary import. From this point Jefferson is led to consider the factors underlying unconsciousness, and the relative roles in its mediation of suspended function in cerebral hemispheres and in the deeply seated cerebral nuclei. He concludes that traumatic stupor is the consequence of a negative or paralyzing lesion of hypothalamus and brain-stem; he cites the experimental evidence therefor, and gives three striking clinical case records of his own that point in this direction. The integrity of afferent pathways to the cerebral cortex is probably also impaired when unconsciousness supervenes on head injury, and the probable importance of these pathways has been stressed by Kleitman in his discussion on sleep and wakefulness.<sup>1</sup>

Jefferson then proceeds to consider the nature of unconsciousness, and prefers the term "parasomnia" as more accurately expressing the picture of deep and abnormal sleep presented by the unconsciousness of the concussed subject. Any student of the vast literature on consciousness, unconsciousness, and sleep must feel that in the forming of clear and accurate ideas on these states we are sadly handicapped by the limitations and pitfalls of linguistics, and by our inveterate human proneness to hypostatize abstractions. The word "consciousness" has only to be uttered, heard, or read, and we at once find ourselves irresistibly entertaining the notion of some elementary and unitary state. Too soon this becomes an "entity" which we seek to "localize" somewhere within the nervous system. On the other hand, the clinical or experimental observer who sees sleep or hypersomnia to follow a local lesion in the neighbourhood of the walls bounding the third ventricle proceeds easily to postulate there a "sleep centre," or, more logically, a "wakefulness centre," the destruction of which allows the subject to lapse into sleep or stupor. In this facile process of anatomizing an abstraction the hypothalamus has become the site of election for hypothetical centres for wakefulness or sleep, and the role of the cerebral cortex in these functions has been correspondingly minimized. In short, there is a naivety in much current thought on these subjects that must convey to the critical student a strong sense of its remoteness from reality. A feeling of this kind is evident in Prof. Jefferson's paper, and indeed it is clear that we must have some deeper thinking as to what precisely we are referring to when we speak of consciousness before we can form any useful ideas about unconsciousness.

Surely there may be more than one mode of consciousness, and this possibility implies that there may be more than one region of the brain, or more than one system of neurons, that functions consciously. May not those who "locate" conscious functioning in the cerebral cortex, and those who—more in the fashion, if not more correctly—would place it in the region of the hypothalamus, both have some measure of reason on their side; and, further, may not the modes of consciousness thus located differ in range and quality? These are questions that must find some answer before we can proceed to find a place in the nervous system for unconsciousness.

A most suggestive approach to these problems has been provided by Kleitman in his evolutionary idea of wakefulness and sleep—a hypothesis that has received too little attention from those engaged in the study and interpretation of concussion and its manifestations. Kleitman draws a distinction between "consciousness of choice" and "consciousness of necessity." The latter is the consciousness of the decorticate dog, which is a fugitive awareness of and response to internal changes and bodily needs—hunger, thirst, and the need to empty bladder or bowels. Of the outer environment there is no awareness, and to events in it no response. Once the internal needs have been dealt with, the animal lapses into sleep again. Consciousness of choice is that aspect of full consciousness of the intact organism which is related to the outer environment. This also is no simple state, but one constantly changing with the flux of environmental stimuli and

<sup>1</sup> *Sleep and Wakefulness*. University of Chicago Press, 1939.

modified by the movement of attention, so that, as Sherrington points out in his Gifford Lectures, "mind" may seem not to attach to a great proportion of the adapted responses to these stimuli.

Is it not possible that consciousness of choice is a cortical, and consciousness of necessity a subcortical, function? It is true that, so far as they go, Masserman's experiments on the hypothalamus seem to show that the hypothalamus is a purely effector organ and not one to which we can with any confidence attribute conscious functioning. There is much in the limited range and in the order of response to stimuli of the stuporous human subject that resembles the consciousness of necessity, but little trace of a consciousness of choice. With the emergence from stupor, elements of consciousness of choice are added progressively, and the range of environmental stimuli taken in and responded to increases. Perhaps the last elements to appear are those which subserve orientation in place and time, and with their return "consciousness" is again normal.

Kleitman traces the evolution from infancy to childhood of the normal diurnal sleep rhythm from the 4 to 5 hour rhythm characteristic of the newborn infant, and he believes this evolution to depend upon developing cortical activity. If it could be made under clinical conditions, it would be an interesting observation to see whether a comparable change from an infantile to an adult sleep rhythm occurs during the emergence from deep traumatic stupor to normal consciousness. If it proved so, it would support the notion of two components—cortical and subcortical—in the complex function we designate by the name of consciousness.

Jefferson concludes finally that the "focus" of unconsciousness is not located in the cerebral cortex but in the hypothalamic region, yet it may be questioned whether the available facts justify this conclusion. That a local lesion in this region is followed by unconsciousness does not rule out the possibility that an associated cutting off of afferent impulses to the cortex may play an essential

and not necessarily impulses from the hypothalamus, there is no anatomical evidence of the existence of a thalamo-cortical pathway, but, as Kleitman suggests, impulses from cranial proprioceptors. It seems highly likely, therefore, that there are yet undiscovered factors in the production of sleep, traumatic stupor, or unconsciousness from subcortical lesions or disorders of function, and the time has not come when we can lightly dismiss the cerebral cortex from an essential and dominant role in the mediation of what—with our simplifying tendencies—we are content to call consciousness—or a suspension of its functions from a correspondingly important role in unconsciousness.

## ANURIA

The association of renal disorder with conditions so varied in nature as pyloric stenosis, blackwater fever, incompatible transfusions, and "crush injuries" has raised the question of a common factor in pathogenesis. Foy and his co-workers<sup>1</sup> make it clear that dehydration is the most constant feature in these conditions. This might come from

excessive vomiting, disturbance of acid-base equilibrium, or diminution of blood volume. These factors, singly or in combination, would cause a decreased renal blood flow and impaired glomerular filtration, resulting in less urine. From this it seems that the oliguria and anuria are not due to blockage of the renal tubules with disintegration products of haemoglobin. The blockage, indeed, would appear to be the result and not the cause of anuria. This hypothesis is supported by the post-mortem findings<sup>2</sup> in a patient with pyloric stenosis who vomited greatly and had all the clinical manifestations of alkalosis, with tetany and uraemia. Lesions in the distal parts of the tubules were morphologically similar to those described in kidneys of patients dying from "crush injury," except for the absence of casts containing myohaemoglobin. This observation supports the view that neither anuria nor renal lesions depend on blockage of the tubules.

Bywaters and Dible<sup>3</sup> attribute the tubular damage to excessive concentration of the glomerular filtrate. Shaw Dunn and his colleagues,<sup>4</sup> on the other hand, lay stress on the reaction of the filtrate. The absence of myohaemoglobin in McLetchie's<sup>5</sup> case rules out this substance as a causal factor, though he rightly points out that some other substance as yet unrecognized may be the toxic agent. He suggests that tubular reabsorption must have strained the tubular epithelium and blood vessels owing to the general dehydration caused by the vomiting. With the small glomerular filtrate and the electrolyte abnormality caused by the dehydration and alkalosis wide differences in the osmotic pressures of filtrate and plasma would naturally exist, and damage of the thin membranes lining tubules and blood vessels might result. There is some evidence that chloride deficiency may itself lead to defective renal function. Perhaps more important is the defective blood supply to the tubules because of dehydration. The fact that the urine in McLetchie's case was acid in spite of the high degree of alkalosis shows how severe the dehydration was. Vomiting causes loss of fluid which contains sodium as well as chlorine, and the latter element is in excess in the gastric juice. To begin with, therefore, carbonic acid is retained in the plasma and tissue fluids to satisfy the demands of the sodium deprived of its chlorine partner. So an alkaline urine is excreted; but with the continued excretion of sodium there results too great a reduction in the osmolar concentration of the body fluids.<sup>5</sup> Since the osmotic pressure must be protected even more than the reaction, the sodium must be conserved, even though the alkalosis gets worse. The outcome is that the urine, reduced in its sodium content, has an excess of organic acid, giving a mild acid reaction. The tubular epithelium is therefore subjected to a double strain. In the lumen the pH is acid, whereas the reaction of the plasma circulating in the tubular capillary is more alkaline than normal. In addition, there is the excessive strain required to maintain osmotic equilibrium with a shortage of the two important ions—sodium and chlorine.

The important therapeutic question is the use of alkali in the treatment of anuria. When blockage is caused by substances, such as acetylsulphathiazole, which are more

<sup>1</sup> *Trans. roy. Soc. trop. Med. Hyg.*, 1943, 36, 197.

<sup>2</sup> *J. Path. Bact.*, 1943, 55, 17.

<sup>4</sup> *Lancet*, 1941, 2, 549.

<sup>5</sup> Morris, N., *ibid.*, 1943, 2, 91.

soluble in alkaline than in acid fluids, alkalis must clearly be given. In other cases, however, the important thing is to increase the depleted blood volume and the deficiency in electrolytes so as to ensure an ample supply of fluid that can be excreted. For this, nothing is better than a solution of sodium chloride with glucose, the former to replenish mineral content of plasma and the latter to promote diuresis. Only in the presence of a severe acidosis associated with chronic renal disease is alkali really necessary, and it is then best supplied in the form of lactate solution.

### PITUITARY CYTOLOGY AND FUNCTION

The pigeon has several advantages for the study of pituitary cytology and its relation to secretory function. First, the period of rapid bodily growth is almost completed before there is any development of the immature gonads, so that the periods of active secretion of growth hormones and gonadotrophin are separate. Again, the sex cycle of the pigeon is accurately known, and can be divided into a resting phase, pre-ovulation and ovulation phases in the female, an incubation period, and a feeding period. The absence of pregnancy and corpora lutea renders the cycle less complex than in higher vertebrates. Thirdly, in the pigeon the importance and function of prolactin are not matters of dispute, as they are in mammals: it may be mentioned here that the secretion of prolactin and of crop milk occurs in males as well as females, as the males share the tasks of feeding the young in the early stages after hatching. These factors have been stressed in their investigations by Schooley and Riddle.<sup>1</sup> Without entering into detailed descriptions of the cytological appearances of the cells from the pituitary glands which they examined from a large number of pigeons killed at various times during the growth and reproductive phases, we may summarize their main conclusions as follows. In the pigeon anterior pituitary, as in mammalian pituitaries, there are two types of chromophil cells which are apparently derived from a single type of chromophobe cell. Schooley and Riddle found that the acidophil cells differentiated during the later part of embryonic life, while the basophil cells matured only during the second month after hatching. This suggests that the acidophil cells are responsible for the secretion or secretions governing the growth processes, while the basophil cells secrete gonadotrophin, which is in keeping with the cytological evidence in other species. During the phase of crop stimulation and crop milk production there is evidence of secretion from the acidophil cells. Whenever functional states indicate a secretion of hormones the cytological condition of the pituitary cells is one of light granulation. Heavy granulation of the cells does not coincide with such functional states, nor are lands in which these cells predominate found to contain large amounts of the corresponding hormones when assayed by implantation. The finding that secretion of prolactin is associated with acidophil cell activity opens up some interesting speculations. Riddle and his colleagues have always been sceptical about the existence of a distinct and separate growth hormone. They have claimed that growth may be under the control of prolactin and/or thyrotrophin, and their investigations of various growth-hormone preparations have always shown them to contain at least small quantities of one or both of these hormones. The fact that crop glands are not stimulated during the initial phase of acidophil cell activity, when the body is growing rapidly,

is explained by the already known insensitivity of the immature crop gland to prolactin stimulation.

A more recent study of pituitary cytology in the pigeon by Koch<sup>2</sup> adds to the three types of cells discussed above a number of different cell types, without clarifying the physiological significance of the findings. The work may be criticized at the outset for the use of Bouin fixation, which is notoriously bad in the study of cytoplasm and its inclusions. The description of new cell types is a tempting hobby for the cytologist, but until such types are clearly related to physiological function they must remain of interest to cytologists alone. The multiplicity of cells described by Koch does not allow so clear a correlation with physiological function as do the descriptions of Riddle and Schooley. Koch's findings agree with those of Schooley in linking the basophil cells with gonadotrophin secretion, and also associate the acidophil cells with prolactin secretion, though here the authors differ on the cytological appearance of the cells during secretion. Koch describes two types of chromophobe cells, but does not pass any judgment on their significance or their relation to the other cells. From the figures given of the large chromophobe cells they may well be degranulated chromophil cells, since they are of the same order of size and show the same sort of vacuolated cytoplasm. The small cells called "kleinzellen" are regarded as effete cells which increase in number with the ageing of the pigeon. These are probably the same as the atrophied acidophil and basophil cells recorded by Schooley in adult females segregated for long periods after egg-laying.

### DISCIFORM DEGENERATION OF THE MACULA

In 1926 Junius and Kuhnt in a sumptuous monograph established as a clear-cut entity the condition they named disciform degeneration of the macula. By stressing the appearances seen at different stages of an affection that always ends with an atrophic disk-like area at the macula, they reduced a mass of purely descriptive designations to a clinical entity with an evolutionary course. They could only indicate but not define clearly the anatomical basis of the affection, but they succeeded in making superfluous such names as senile exudative macular retinitis, senile macular degeneration, pseudo-tumour of the macula, haemorrhagic macular retinitis, and many others. Histological studies on disciform degeneration of the macula have appeared with surprising frequency, and they all agree in showing connective-tissue proliferation in the deeper layers of the retina, disturbance of the pigment epithelium, thickening with or without ruptures in the elastic membrane, and transudates between the retina and choroid, sometimes quite massive. These findings are in the main confirmed by Holm,<sup>3</sup> whose histological study is the basis of a critical survey of the literature, which leads him to deny the validity of the conception of disciform degeneration as a distinct clinical entity. Holm's patient showed the not infrequent association of retinitis circinata, and histologically this proved to be due to subretinal fluid and not to intraretinal changes showing fatty and hyaline degeneration, as is commonly observed. He stresses that identical fundus pictures may have different anatomical backgrounds, and argues from this that the retina and choroid have a limited range of reactions to a variety of stimuli. This is no doubt true, but we doubt whether he should argue from this against the conception of disciform degeneration as a distinct entity, even though Holm can show that various

<sup>1</sup> Cold Spring Harbor Symposia Quant. Biol., 1937, 5, 165; Amer. J. Anat., 1938, 62, 313.

<sup>2</sup> Arch. Gyräk., 1941, 172, 1.

<sup>3</sup> Acta ophthal., Suppl. XIX, Copenhagen, 1942.

observers have wrongly regarded some cases as instances of disciform degeneration. It does not add to clear thinking to link the essentially "senile" condition of disciform degeneration of the macula with Coats's disease, which is essentially "juvenile" and not a clear pathological entity.

### ARTERIAL OXYGEN AFTER PULMONARY RESECTION

The lungs of a healthy person are said to contain ten times as much aerating tissue as is necessary for minimal requirements. Little, however, is known of the effects of pulmonary resection on the oxygen saturation of the blood, and it is important that this should be carefully studied in view of the numerous operations of lobectomy and pneumonectomy now being performed. Maier and Cournand<sup>1</sup> have made several hundred determinations of the arterial oxygen saturation after these operations, and their conclusions are of much importance. Blood was taken from the brachial artery for the estimations, which were not made when recent administrations of drugs or of oxygen might cause inaccuracy. Seventeen cases of pneumonectomy and 21 of lobectomy were studied.

In most of the pneumonectomy patients oxygen saturation was but little impaired, and, in fact, in those with a smooth clinical course it was normal within two or three days. In two cases prolonged oxygen unsaturation was observed. In the first this was associated with a large pleural effusion on the side of the operation, and restoration of the mediastinum to the mid-line by aspiration of fluid resulted in a rapid return of the arterial oxygen saturation to normal. The findings in the second case were most significant. The patient was a 62-year-old man with emphysema of both lungs who underwent left pneumonectomy for a carcinoma. The operation was well borne, but the arterial oxygen level continued to drop gradually during the next three weeks. Investigation of the pulmonary function showed that the residual air volume had reached the very high value of 70% of the total lung volume. This was due to overdistension of the remaining lung, which had ballooned over so much to the pneumonectomy side that ventilation was impaired. As soon as this was corrected by air refills on the operated side the oxygen saturation rapidly improved. This most interesting observation supports Lester and Cournand's<sup>2</sup> finding that pulmonary function after pneumonectomy was much better in those patients in whom marked compensatory emphysema did not occur.

The disturbance of oxygen saturation is greater and returns to normal more slowly after lobectomy than in uncomplicated pneumonectomy. Most cases show anoxic anoxaemia for a week at least, and when expansion of the remaining lobe is slow, or when there is compression from fluid, oxygenation is interfered with for longer. Retention of bronchial secretion and atelectasis may lead to severe anoxia. The remaining lobe appears to act as a shunt for some time, and even when it is aerating satisfactorily oxygen absorption from it is deficient. These findings are in conformity with ordinary clinical experience after lobectomy. Nevertheless, Maier and Cournand stress that clinical criteria of anoxia are unreliable, as is repeatedly shown by determinations of arterial oxygen. Dyspnoea and cyanosis are not accurate signs, for severe anoxia may exist in their absence. The importance of other signs and symptoms of oxygen lack, such as those seen at high altitudes (e.g., restlessness, mental confusion, and hallucinations), is often overlooked, and the authors suggest that,

instead of waiting for anoxia to develop, determinations of arterial saturation should be a routine after pulmonary resection so that the condition may be recognized in its earliest stages. In any case it is clear that, after both pneumonectomy and lobectomy, oxygen therapy is often desirable for much longer than is commonly thought. After pneumonectomy correction of mediastinal displacement to either side is important.

### OPIUM TRAFFIC IN THE FAR EAST

A recent written reply by the Secretary of State for the Colonies has reopened questions which occasioned fierce debates at the second Geneva Conference on Opium in 1925. It will be remembered that the American and Chinese delegations withdrew from the Conference mainly on the grounds that opium-smoking in the Far East had not been suppressed or restricted in the way prescribed by the Hague Opium Convention of 1912, and because the production of opium was not to be limited to what was required for medical and scientific purposes. The policy now announced on behalf of the British Government is the prohibition of opium-smoking in the British territories now in enemy occupation in the Far East and the abolition of opium monopolies therein when they are reoccupied, and also that the limitation of production of opium be considered. The principles for which the American delegates contended in 1925 were: "(1) That if the purposes of the Hague Opium Convention are to be achieved according to its spirit and true intent it must be recognized that the use of opium products for other than medicinal and scientific purposes is an abuse and not legitimate, and (2) that in order to prevent the use of these drugs it is necessary to exercise the control of the production of raw opium in such a manner that there will be no surplus available for non-medicinal and non-scientific purposes." The chief opposition to these principles came from India because of the opium purveyed by the Government for eating or for export trade. Moreover, income was derived from opium monopolies in the Malay States, Straits Settlements, and Borneo which the Crown Colonies were loath to surrender. M. Zahle, the able president of the Geneva Conference, in his final speech said: "No voice, I believe, can be raised against the justice of the principles enunciated by the American delegation"; and observed: "The producing countries realize that in total they are providing far more drugs than the world needs."

The world production of opium has been estimated at not less than 2,500 tons a year, while the world requirement for legitimate medical purposes is probably less than a tenth of that amount. The principle of limitation of opium production to medical and scientific purposes has been accepted by both the Advisory Committee of the League of Nations on Traffic in Opium and also by the Assembly of the League. The British delegates to the Hague Opium Conference of 1912 were instructed when attaching their signatures to it to add a declaration that the convention, if ratified by His Britannic Majesty's Government, shall apply to British India, Ceylon, the Straits Settlements, and Hong Kong in the same way as applied to the United Kingdom. In Great Britain the Dangerous Drugs Acts of 1920 and 1923 were introduced to give effect to the Opium Convention signed at The Hague on Jan. 23, 1912, and "to bring under control throughout the world the traffic in opium and cocaine and the preparations derived from them, and to restrict their use to medical and other legitimate purposes." It is to be hoped that the new declaration of policy may tend, if tardily, to achieve this beneficent object.

## THE CHRONIC MEDICAL CASE IN THE ARMY

BY

J. W. TODD, M.D., M.R.C.P.

Major, R. A.M.C., Medical Specialist

## Types of Cases and their Treatment

Of 500 consecutive chronic cases which I recently saw in the out-patient department of a military hospital there were 146 with frank psychoneurosis, 95 in which the complaint was chiefly of dyspepsia, 60 with some kind of "rheumatism," and 101 with bronchitis. 40 men had neither apparent disease nor appreciable symptoms, and had mostly been referred because of the accidental discovery of some such benign phenomenon as a systolic murmur. Of the remaining 58 cases, 6 had migraine, 5 pulmonary tuberculosis, 4 asthma, 4 syncopal attacks, 4 epilepsy, 4 the sequelae of concussion, and 3 the sequelae of meningitis. There were not more than two examples of any other condition.

Of the 146 psychoneurotics, the main manifestation of 90 was the "effort syndrome." Of the 95 dyspeptics, 19 had radiologically demonstrated peptic ulcers, 17 of which were duodenal, one pyloric, and one jejunal following gastroenterostomy. Many of the radiologically normal cases had marked neurotic traits. Of the 60 cases of "rheumatism," the symptoms of the majority were wholly or partly psychogenic. The 101 bronchitides were the most "organic" group of all, and many of them had demonstrable chest disease. However, the conclusion that I often reached was that a man's chest was no worse than that of thousands of his fellows, and the real reason which had brought him to the out-patient department was his associated psychogenic symptoms.

Such cases as these are sometimes admitted to hospital for investigation and treatment, and they may remain for a long period. It is not uncommon to see men who have previously spent many months in one or more hospitals. Although hospital treatment may cause a temporary relief of symptoms, I have yet to hear of a single soldier with one of these chronic complaints whom it permanently benefited, except those with such conditions as peptic ulcer, for which they were discharged from the Service. If any actual medical condition is unimproved by a stay in hospital it can hardly be doubted that the psychological state is sometimes made worse by it. The men may become bored, depressed, and hypochondriacal, since they tend to think that as they are being kept in hospital they must be very ill. Their presence in a ward, too, would seem to have a bad effect on the more acute and recoverable cases there.

The conclusions from these considerations are, then, first, that the main trouble in many soldiers suffering from what are usually considered chronic medical complaints is psychiatric; and, secondly, that, whatever be the nature of their disease, they should rarely, if ever, be admitted to hospital, except in a few cases, merely to await discharge from the Service.

## Disability and Diagnosis

When a man's condition is being considered by specialists or medical boards it is the usual practice to expend much effort in deciding whether or not he has organic disease. If his symptoms are thought to be psychogenic a soldier is often reported as having "nothing the matter" or that "he only thinks he is ill." This attitude of minimizing the psychological condition is curious, for it seems obvious that among the qualities which are of quite supreme importance to the fighting man are the psychological ones. Of such qualities, those which are involved in a man's efficiency as a soldier may be roughly divided into three—his intelligence, his knowledge, and his character. The quality a deficiency in which will result in the greatest military disability is character, and most men with neurosis manifestly do have a gross character defect. If, on the other hand, organic disease is found to be present in a soldier he may be lowered in category or discharged from the Service even when his actual disability is slight. Among chronic medical cases the commonest examples of this are probably recovered pleural effusion, healed pulmonary tuberculosis, hyperpiesia, persistent albuminuria which is thought to be due to chronic nephritis, and the presence of a heart murmur deemed to be organic.

There should here be only one reason for lowering the category—that although the man in question has little disability now, he is likely to develop disability in the near future. In the conditions I have mentioned it would not as a matter of fact be probable—indeed, it would be quite unlikely—that such men would soon become disabled, and therefore they should not be put into a category lower than their actual disability warrants.

Another reason which is put forward against retaining such men is that, small as the chance of their breaking down may be, it is more likely to happen in the Army than it would be in civilian life. Even if this be true, when one considers that the Army is in being to fight a war in which thousands of its members will be killed or maimed this argument seems to show the lack of a sense of proportion.

Organic diagnosis thus seems commonly to occupy too prominent a place in the consideration of the chronic case, to the exclusion of disability, which is what really matters. The principle which should lie behind diagnosis is merely the decision whether progressive or severely recurrent diseases are present. If they are not, the subtleties and refinements of diagnosis can be forgotten. It follows that any investigation which does not help to make that decision is superfluous. A good example of such an investigation is the gastric analysis which merely provides an opportunity of labelling a man with an absurd diagnosis like "hyperchlorhydria." Many psychoneurotics undergo investigations directed to the stomach, heart, bladder, or other organ the function of which has been upset by the psychological disorder. In such cases it seems that the doctor has failed to look at the man as a whole but has concentrated his attention on some small part of the body.

Most chronic cases really need either no investigation at all or just one. A few need two and very few more than two. Provided that there is co-operation between the clinician and the radiologist and pathologist, it is possible to do all these with a maximum period of one night in hospital. I therefore suggest that no chronic medical case should be admitted to hospital for investigation. I previously concluded that virtually none should be admitted for treatment.

## Disposal

The soldier with a chronic complaint may be so obviously unsuitable for fighting that he is discharged or lowered in category, though the official reason for doing this is often the presence of some physical condition and not the psychological defect which is so frequently the main cause of his disability. Many of the bad cases are retained in the Army and given such unilitary duties as cleaning billets, emptying latrines, and picking up paper. When the question of actually discharging men for psychological disorder comes under consideration by a medical board, the members of the board often feel very strongly that it is unfair and unjust that they should be allowed to escape from the dangers and discomfort of a soldier's life. Although such men are usually quite useless to the Army, it does seem very wrong that they should be sent back to their homes with the halo of being poor invalids.

The actual assessment of the degree of military disability is not a medical problem at all. A soldier's officers are in a far better position to judge it than is, say, the medical specialist, who only has time to see him for 10 or 20 minutes in the middle of a busy afternoon. The officers constantly observe the man on exercises and see whether, for example, he can go over an assault course or march 30 miles or shoot to hit. The specialist, on the other hand, has to deduce from the man's condition what he thinks he ought to be able to do. This may at times bring him to quite wrong conclusions, and perhaps to say that a man is fit to carry out all the duties of an A.I. soldier when he has actually never succeeded in doing so. The following scheme would, I think, supply a better method for the classification of soldiers than does the present one.

After recruits have been in the Army long enough for those in charge of them to form a proper estimation of their capabilities, those who are in any way unsatisfactory should be put to various tests. For example, it might be determined how far they are able to march in full kit, in what time they are able to run, say, a mile, how accurate they are with a rifle and other weapons, and so on. As is already done, they should also, of course, be given an intelligence test. Every man unable to attain the top grade should be

seen by the M.O., who would supply a certificate stating whether or not he has a progressive or severely recurrent condition. If such conditions are suspected the man should be referred to the specialist. All men not so afflicted, whatever they happen to be suffering from, would then be graded into various lower categories, purely according to their abilities to function as soldiers.

If an officer later on considers that one of his men is unsuitable for his existing category he should again be put through these various tests and an appropriate form filled in. In this case there might be also added a statement as to the number of times he has been in hospital or excused duty during a specific period, whether he is offensive to others (as in enuresis and chronic bronchitis), and an estimation of his character, which the officer should be in an ideal position to judge.

Any man who functioned so badly that it appeared doubtful whether he could be of any value to the Army at all would be seen by a disposal authority. This body would decide whether or not there was any place in the Army which he could fill. If there were none, he would return to civil life. If, later, the needs of the Army were to change he could be recalled. This kind of procedure is already being adopted in the case of permanent Category C men under a recent A.C.I.

The only men who could not be dealt with by this machinery are those suffering from conditions which are rapidly progressive or recurrent. They would form the proper material for a medical board, since the assessment of their likely rate of progression or recurrence is a truly medical problem.

This scheme I have outlined would evidently mean a great saving in medical man-power. If it were in operation the physician would not spend his time in fruitless endeavour dealing with the chronic sick. He would instead be able to spend his days in what should be his proper function—caring for acutely ill men and returning them to their units as soon as possible as fit and fighting soldiers.

### Conclusions

Chronic medical cases should never be admitted to military hospitals for investigation and rarely for treatment.

The main disability of most chronic "medical" patients is psychological, whatever diagnosis is attached to them.

Psychological disorders cause more serious military disability than do most of the chronic organic diseases seen in soldiers.

A man should be put permanently into a lower category than his disability would warrant only if he has a rapidly progressive condition or a recurrent condition which is likely to be sometimes severe.

Disability should not be assessed by specialists or medical boards. All men, except those with progressive or severely recurrent conditions, should be classified by the results of tests designed to show how they function as soldiers.

I wish to thank Lieut.-Col. E. G. Holmes, R.A.M.C., Major J. H. Malloy, R.A.M.C., and Capt. F. H. Scadding, R.A.M.C., for many helpful suggestions.

All German men and women in certain age groups hitherto not employed on national service have been called on to report for duty (*Reichsgesundheitsblatt*, 1943, 21, 351). A large number of these persons, especially women, will thus be entering into a contract of service for the first time. The Labour Controller has issued the following order, which is based on the order of the Reich Health Leader: "The chief medical officer of the Labour Office in each State makes immediate contact with the competent medical chamber. If the necessity should arise, the competent medical chamber can undertake the examination of the medical reports if a local agreement to this effect has been arranged between the chief medical officer of the State Labour Office and the competent medical chamber. . . . It is absolutely essential that no error should occur in allocating women to work which might reduce their fertility. . . . The doctors primarily concerned with this problem are doctors who have placed themselves at the disposal of the centres for childlessness in marriage, the doctors in charge of State and municipal gynaecology and midwifery training centres, etc. Attention is drawn to the fact that even with the most careful investigation of legitimate complaints the present circumstances demand harshness in the employment of women. Also the earlier experiences of the RADWL [Young Women's Branch of the Labour Service] showed that permanent damage is hardly to be expected from amenorrhoea resulting from employment. It is therefore neither a reason for exemption nor an excuse for release from employment. . . . I am convinced that the German doctor also in this new sphere of employment will prove himself as hitherto a political protagonist who serves Fuehrer and people with a sense of responsibility and in this way helps to achieve total victory."

## A CLINIC IN THE BUSH

[FROM A CORRESPONDENT]

It all began from laundry baskets. Matron complained the baskets for clean and dirty linen, which the "mammies" carried on their heads, were too small and that too much time was wasted carrying the laundry backwards and forward. The markets and the shops of the capital yielded no baskets—or anything else of much use, for that matter—so it was necessary to find someone to make them.

Passing through a large bush village on one occasion, trying to buy eggs to relieve the monotony of beans and bacon or soya sli for breakfast, I asked a "boy" who could speak a little English there was anyone in the village who could make baskets. "Yes, mastah, my father he make fine fine baskets plenty." So I was taken into a compound, and, threading through narrow paths between huts, from which innumerable children ran out, past women and girls grinding the Koos in large wooden mortars with pestles nearly as big as themselves, I arrived at a very dark hut inside which a venerable but dirty-looking old man in a ragged shirt sat weaving a mat, with a selection of wives round about, from a buxom damsel of 17, well on the way towards her first-born, wizened women of 40 or 50, and children from babies in arms grown-up men like my guide.

The old gentleman spoke no English, but after "plenty palaver" he agreed to make enormous baskets at four shillings a time. Very fine baskets they were too, well worth the money and exactly what was wanted for the laundry. He made about four or five a fortnight and we wanted eighteen. In the middle of making them "I went for bush to buy a cow," so his wives informed me, and the transaction took him about three weeks. All in all, then, my dealings with the old gentleman lasted for a considerable time, but before long the purchase of baskets took a very minor place in my business in this village.

It was on one of my early visits to take delivery of the baskets that the son, my interpreter, drew my attention to his bandaged leg, and asked me for "white man's medicine," as with this he could not work. I confess that at my next visit I had forgotten all about his leg and had brought no remedies, but I silently reproached that the "great white master" had failed him in such that I could not forget again.

He had a typical tropical ulcer, which seemed to be based on yaws sore, for he had signs of previous yaws on his feet—fissures and punched-out scars. So the next time I brought a supply of succinyl sulphathiazole powder, a syringe, and a flask of sobil. His treatment was very satisfactory, but even when quite cured I did not return to work, though he often demanded a "paper" recommendation for a job. Actually he remained my faithful doctor and almoner at the clinic until I left the colony. On my next visit eight or ten adults and children with bad sores on their legs presented themselves. They were given "chucks" (injections) at their sores were bandaged up with powder.

The effect was magical—so much the treatment as the way the news spread. Soon what had begun as a benevolent gesture became a serious moral obligation not only for that village but for all the villages round, whose sick walked quite long distances to get treatment; what at first took three minutes soon became three and a half hours of really hard work. Every Saturday afternoon I spent the time with the villagers, until I was sweating and exhausted, and my medicaments, which had to be increased in quantity weekly, were finished.

One week when I was sick a colleague took my place, "just to see what it was like." He saw all right, but, like me, felt that he could not go back on this self-imposed task, and at the end of my stay in the colony we both went and worked all out for the whole of the afternoon. There is no doubt that the villagers were grateful, and sometimes they tried to express their thanks, and although their efforts were clumsy they were none the less sincere. Our missionary zeal, however, was not without ulterior motive, for we let it be understood that "susikilo" (eggs) and other produce were not unacceptable. For six months we never lacked an egg, sometimes two, for breakfast, and had enough over to give some to our friends. An occasional chicken, in season mangoes, oranges, and pawpaws, more than we could eat, made a lot of difference to the meagre and monotonous diet provided by the supply authorities, who had not the graft of medical skill enjoyed by us.

### Crowded "Out-patients"

Our "consulting room" was primitive in the extreme. At first we held our sessions outside a hut, with no table or chair, partially protected from sun and later from rain by the edge of the thatched roof, with literally dozens if not hundreds of men, women, and children crowding round, laughing, talking, gesticulating, so that it was well-nigh impossible to hear oneself speak or to move one's arms. As the numbers grew and the rains came on in earnest the

arrangement became impossible; we had to be protected from both our patients and the weather. We brought a table and a couple of chairs and were allowed the use of a slightly larger and more stable hut, *pro bono publico*. Here we sat in a dark and stuffy inner room while half a dozen stout bodyguards held the seething multitude at bay. They were fairly successful with the men, but with the women and children, who were kept waiting until the men had been attended to, all bounds were soon broken, and we were almost submerged by a mass of solid, black, but clean flesh, even though they were covered with yaws ulcers.

The domestic habits of these people are filthy in the extreme, but in their persons they are far cleaner than those whom one is accustomed to see in a hospital out-patient department at home. This cleanliness was what really made the clinic possible, and accounted for the absence of calamities from our very unorthodox treatment. Lately we were giving 150 to 200 intramuscular injections every session; there was no time for asepsis, and the only cleaning a needle got was passage through the skin of the next patient; yet we never had an abscess or even a septic pimple. This cleanliness was not due either to an absence of clothing, for it was wonderful how many layers of cloth were unwound, especially from the women, even in that tropical climate. They always wanted to appear pregnant, as that was their most honourable condition, and if they were not they bunched up the innumerable layers of cloth in which they were wrapped in order to add verisimilitude to an otherwise unconvincing shape. Modesty was curious; after the first moment of confusion the grown-up women and older girls showed none, though the little girls from about 5 to 10 were much more diffident. The men were very shy, especially if they thought that their women were looking at them over the fence, while some of the old men were as coy as any delicately nurtured English maiden.

Our teachers of medicine would have been horrified at our rough-and-ready methods, and the traditional sixpenny practice with hands up for cough or belly-ache would almost appear scientific in contrast. Still, on the whole it worked, and anyway it was the only form of treatment these people had a chance to get. It certainly taught us about the diseases indigenous in that part of the Tropics in a way which no set lectures and demonstrations in an organized course could have done.

### Prevalence of Yaws

By far the commonest disease we were called upon to treat was yaws. It must affect nearly 100% of the children. Generally it was in the secondary stage, with the characteristic ulcers with heaped-up edges, which, with secondary infection, often spread widely and deeply as tropical ulcers. These yaws are chiefly on the feet and legs, but also on the extensor surfaces of the elbows, and, especially in women and children, over the sacrum and buttocks and in the anal folds. It was quite remarkable how these yielded to half a dozen weekly injections of 1 c.cm. of sobita. Of course it was impossible to do Kahn tests and we probably did not cure the disease, but at least we removed the symptoms for a time. Sometimes the sores were so thick all over the body that there was scarcely room to make the injection, but even these melted away under the influence of the sobita, and the tropical ulcers, once the secondary infection was checked by the succinyl sulphathiazole powder, closed up with astonishing rapidity in many cases. In fact this became a therapeutic test of the nature of the ulcer. In nursing mothers a severe mastitis was often seen, which cleared up equally satisfactorily with sobita.

Other manifestations of yaws were swollen, intensely painful joints, periarticular nodes, and in older people the aching pains in the shafts of the bones and headache, which was a marked symptom. These pains were generally easily diagnosed by the concomitance of sores on feet, and the patients always expressed themselves better as the result of the sobita.

Fibrositis existed, but was not often seen, except where there was a clear history of severe strain or other trauma. Gonorrhoeal arthritis was not very uncommon, but arthritis of the rheumatoid or osteo-arthritic variety was very rare, although it did occur. The halangeal deformities of very late yaws were not dissimilar to a chronic rheumatoid hand. Acute rheumatic infection was supposed to be non-existent, but two young women with undoubted mitral stenosis were picked up in another clinic.

The most interesting disease was trypanosomiasis, which was not supposed to exist in that part of the colony. Although not common, there was seldom a week when we did not discover one or more children or young adults with dull, mask-like, almost Parkinsonian features, functional ptosis, and enlarged glands, especially in the posterior cervical triangle, complaining of headache, lassitude, and fever, and sometimes of sleepiness, though this latter a late symptom as a rule. We tried to get them to come up for blood puncture and confirmation to the hospital, where the subsequent antitrypal and tryparsamide medication could be given intravenously, as we did not dare to give intravenous injections under

the septic conditions of our clinic. One of the most interesting cases was that of a small boy who had all the appearances and behaviour of a low-grade imbecile, but who also had trypanosomiasis. Under treatment he developed in a most remarkable way, and, although probably still backward, was raised far above the imbecile class. It was impossible to test the degree of deficiency with no basis of common speech, for we had Mandingos, Jollofs, and a few Fullahs, all speaking quite different languages.

### Incidence of Other Diseases

Skin diseases were common—scabies, tinea, and some conditions which defeated our powers (admittedly limited) of dermatological diagnosis. Leprosy was rare, but we did see one or two cases. Elephantiasis was also rare, but a few cases turned up, often confined to one foot or leg and not often in the scrotum. Oedema was not uncommon, mostly of hepatic origin; malaria, amoebiasis, and other tropical maladies did not give the liver much chance of remaining healthy. Dysentery was for the most part mild, and as sodium sulphate was equally efficacious for this and for constipation our therapeutic resources, necessarily very limited, were in this respect economized.

A large proportion of children between 2 and 12 had enlarged malarial spleens, but after this age splenomegaly tended to disappear and malarial attacks, though they did occur, passed almost unnoticed, they were so mild. It was interesting to note that the almost universal pot-belly in the young children was scarcely ever due to an enlarged spleen, as we at first suspected, for the spleens were not large enough to cause so much distension. Umbilical hernia was very common, probably due to the crude methods of separating the cord, and consequently the abdominal muscles were at first very lax, until head-carrying of weights, begun at a very early age, strengthened all the muscles of the trunk; in children who were breast-fed for two or three years some of the distension was just plain fat.

Chest conditions were often seen: a few cases of tuberculosis, which went downhill very fast; many cases of not very severe bronchitis; and a few patients with pneumonia, most of whom recovered quickly, generally walking about on the fourth or fifth day and sometimes not lying up at all. Heart disease was represented by a few congenital abnormalities and one or two final breakdowns, but except for the two cases of mitral stenosis already mentioned and an occasional aortic incompetence, presumably syphilitic, there was none of the wealth of clinical material so often met with in out-patient departments at home.

Organic nervous disease was practically non-existent, because there is little nervous syphilis and yaws does not attack the nervous system, but we had one pathetic old gentleman with paralysis agitans, who was convinced that an injection of sobita would cure him at once. Mental disease was represented by very occasional cases of schizophrenia. Juju hysteria is not met with to any extent in the colony. Venereal diseases were not very common in the villages and were chiefly gonorrhoea and lymphogranuloma; the glands in the latter disease sometimes blocked the lymphatics, causing unilateral oedema; these cases we referred to a V.D. clinic which we held in another village. Syphilis was difficult to diagnose. This is not the place to discuss whether yaws is really syphilis or syphilis yaws, but syphilitic lesions such as we are accustomed to at home were not met with to any extent. Gonorrhoeal (?) ophthalmia was not uncommonly seen. It was so severe in some cases as to make treatment appear useless, but 10% protargol seemed to help even these apparently hopeless people so much that from being quite blind they were obviously able to see. It must be remembered that they do not read or do any fine work, so even a small degree of vision was reasonably adequate. The same treatment was successful in trachoma, which is often found here, although it is very mild, with remarkably little disabling effect.

Otitis media was rare in spite of the prevalence of upper respiratory catarrh, and we saw no mastoiditis or other severe aural complications. Septic teeth and tonsils were not often seen, but when they did occur, or rather when the people were led to complain about them, they were bad, and some of the dental abscesses were appalling.

This bush clinic was really a commonplace out-patient department, with the common and interesting diseases characteristic of a tropical instead of a temperate climate; but it was instructive, as all such out-patient departments must be. Our diagnosis and treatment were severely limited by the total absence of modern facilities and ancillary services, but on the other hand perhaps it was good for us to realize that clinical medicine could still do something without them. The chief lesson to learn, however, was that from the humanitarian point of view we have a duty as a profession to bring some relief and healing to these simple, kindly, and trustful people. From the scientific point of view, what a wealth of untapped material at all stages of disease is to be found ready to our hands, especially if we go out to the people, instead of sitting still and waiting for the people to come to us, often when they are beyond relief.

### The Changing Character of War Wounds

SIR,—A recent tendency has been noticeable on the part of those recording experiences of war wounds to ignore a factor which would appear to influence results of treatment, and may, unless due consideration is given to past wars in the light of the present one, easily be overlooked. The more favourable results of the treatment of wounds in this war when compared with those of 1914-18 are generally ascribed to such factors as earlier excision, the sulphonamides and now penicillin, tetanus toxoid, early plaster fixation, special mobile surgical teams, etc. All of these are obviously highly contributory, but there are still others which may be operative. Among these the environment in which wounding occurs is no doubt important, and we should not lose sight of the character of the wounds themselves. For the most part the present war wounds are found to be singularly free from pieces of uniform, underclothing, webbing and leather equipment, badges, and the like, which were so frequently seen in the last war and were such a heavy source of contamination. Inquiry into the reason for this difference in the character of the wounds at once suggests that this is due to the difference in nature of the explosives and the missiles used.

When Lord Nelson was mortally wounded by a musket ball which, striking his left epaulette from above, fractured the spine, traversed the spinal canal, and lodged in the muscles of the back, the ball carried in with it "a portion of the gold lace and pad of the epaulette, together with a small piece of his lordship's coat" (Richard Clarke's *Life of Nelson*, London, 1813). These materials were found firmly attached to the ball as it lay embedded in the muscles. From Trafalgar until the 1880's there was little fundamental change in small-arm ballistics, but about that time high-velocity rifles were first used. These burned "smokeless" powder and fired small and hard projectiles at high velocity which tended to cut through, rather than punch out and carry pieces of clothing or other covering material along with them. With their use and later still high-explosive shells, deep contamination by clothing or other materials traversed by missiles took place less often, but nevertheless did not disappear entirely, as was amply shown during the years 1914-18. The projectiles used in the present war, however, are remarkable for the still higher velocities imparted to them—velocities which have never hitherto been attained and are probably in some cases of the order of 8,000 or more feet per second. At the same time the materials of which these missiles are composed are for the most part relatively light as compared with lead. The result is that many war wounds to-day are caused by small fragments of relatively light material travelling at an extremely high velocity. These cut cleanly through whatever coverings they meet, and in doing so undergo rapid change in momentum so that they relatively soon come to rest. Their wound of entry may be difficult to find, and as they are very hot they are relatively sterile and often do little damage.

I suggest, therefore, that in any comparison of the results of treatment of the casualties of this war with those of the last the changed character of the wounds caused by modern projectiles should be given due consideration.—I am, etc.,

Bristol.

LAMBERT ROGERS.

### Thymectomy for Myasthenia Gravis

SIR,—The report by Dr. Maurice Nellen on a single example of thymectomy for myasthenia gravis (Dec. 18, p. 778) is of much interest as additional evidence that remission of symptoms may follow the operation. It may be questioned, however, whether it is really wise to publish isolated instances of treatment in a disease where so many unknown and doubtful factors are concerned as are found in the clinical complex known as myasthenia gravis. It is certainly unwise, I think, to conclude, as Dr. Nellen has done, that there is enough evidence now "to warrant a thymectomy in every case of myasthenia gravis." In collaboration with Dr. James Carson I have, since Feb., 1942, performed the operation of total thymectomy twenty-five

times, and a brief report of the first twelve was given at meeting of the Neurological Section of the Royal Society of Medicine in Nov., 1942. This comparatively large series of operations will, we hope, ultimately form the basis for a detailed account of the surgery of the thymus gland and its relation to myasthenia gravis. The results, however, are variable, so that it would be equally misleading to publish a single failure or a single success. We feel that we are treading on uncertain ground, and although we are encouraged to proceed cautiously with careful choice of subjects, we far from subscribing to Dr. Nellen's conclusion that thymectomy should be done for every patient with myasthenia gravis.—I am, etc.,

London, W.1.

GEOFFREY KEYNES.

### The Abduction Splint

SIR,—No doubt Mr. Souttar in his most interesting Bulletin lecture "Physics and the Surgeon" expected some criticism of his remark about the "so-called abduction splint." One cannot resist parrying his slight sword-thrust, for it is obviously misdirected. The primary purpose of the abduction splint—used, for example, in the treatment of tuberculous hip—is not to produce abduction but is to control the hip and to give immobilization. This immobilization and control involves careful attention to both lower extremities and to the pelvis, and the splint does in fact maintain the hip-joint in whatever position the orthopaedic surgeon determines to be best for the particular joint in question. The abduction splint and the patient form one complete mechanical system, and counter-traction being arranged with scrupulous accuracy for the purpose mentioned.

Mr. Souttar need not lower his voice when addressing orthopaedic surgeons: we welcome criticism.—I am, etc.,

Exeter.

NORMAN CAPENER.

### Cerebral Herniae and Surgical Decompressions

SIR,—Your reviewer of the handbook of surgery by Handfield-Jones and Porritt (Dec. 18, p. 781) disagrees with the suggestion that the term cerebral hernia should not be used for surgically made decompressions. These decompressions properly made are under cover of functioning muscle with conserved nerve supply, and are thus under a very good measure of control and differ from an unrestrained brain protrusion covered only by skin or granulation layer.

There is an essential difference here, and to call one a decompression and the other a hernia is worth while. The maker of a good decompression is saved from the stigma of being the creator of a real hernia, which is, or rather was, an indication of slovenly technique.—I am, etc.,

London, W.1.

A. DICKSON WRIGHT.

### Omens of Influenza

SIR,—Commenting on your leading article on influenza (Dec. 4, p. 717), where you say, "the phenomena which determine epidemic influenza are still largely unknown," Dr. A. Garvie suggests that epidemics may often follow outbreaks of common colds (Dec. 18, p. 793).

May I suggest that a more useful alternative would be to attempt to predict epidemics by some combination of the two main theories: the seasonal (i.e., meteorological) and the intrinsic cyclical one of Brownlee in its two-phase modification (Webster, *Edinb. med. J.*, 1939, 46, 591). Thus the last peak over 300 was in the week ending Feb. 15, 1941. Should the present peak have been reached at 1,148 (week ending Dec. 11) the interval is  $4\frac{1}{2}$  periods of 33 weeks; the half-period being 15 weeks, as often is the case in both influenza and cancer.

It is also of interest that the present epidemic is seven years (to a month) from the 1937 January peak, and 11 years from the 1933 epidemic. Influenza here seems to show a similar "long-period" to that discussed recently by me in cancer (Dec. 4, p. 720).

Swine influenza breaks out in such widespread areas of the United States simultaneously that only a meteorological "trigger" can be suggested as an essential causal factor. A similar correlation in human influenza is suggested by study of the meteorological phases at large epidemics, as in the marked "polar front" shown in chart form by Sir Napier Shaw

in his *Drama of Weather* (1933, Fig. 72, p. 196) for Feb., 1929. Epidemics are more likely to occur when such a meteorological environment, with its associated biochemical reactions, and other lowered resistance factors coincide with one of the periods (or half-periods) on the cyclical theory of Brownlee-Webster. The present epidemic in its time of arrival supports such a viewpoint.—I am, etc.,

London, W.1.

J. H. DOUGLAS WEBSTER.

### Secondary Organisms in the Lungs in Influenza

SIR.—Your leading article on staphylococcal pneumonia (Dec. 18, p. 783) is evidence of a renewed interest in the secondary invaders of the lungs in influenza, and especially in the very dangerous *Staphylococcus aureus*, which one or two of us found in 1918-19. You quote from a short paper of mine in the *Lancet*, but this was a preliminary note on what we were then finding in Malta. I really write this to say that a somewhat fuller account, with records of a larger number of cases, was published in the *Journal of the Royal Army Medical Corps* for Feb., 1923. One striking comparison showed that while *Staph. aureus* was present in the sputum in 27% of 187 cases of bronchopneumonia, it was found in 83% of 30 fatal cases. Perhaps I might quote from the conclusions of this paper:

"The results obtained give no clue to the nature of the primary infection, but they show to what an extent this primary infection reduces the resistance of the tissues to the attack of the secondary invaders. The occurrence of *Staph. aureus* in a large proportion of fatal cases [in Malta] has not, I think, been recorded as a feature of the epidemic in other places. . . . It is evident from the numerous published accounts that the secondary organisms found in the lungs vary in different localities, and difference in case death rates may be due to difference in the secondary invaders."

—I am, etc.,

Dundee

ADAM PATRICK.

brother, aged 11, went down with fever, vomiting, and very marked jaundice. This last boy had had no prodromal symptoms whatever, though he had the worst attack of the three.

Altogether I saw eleven cases of epidemic hepatitis in the next four months, mainly in the first six weeks, though I knew of others. For example, I attended a girl aged 9 during the acute phase of a moderately severe attack from April 20 to 26. On the last date her twin sister, who slept with her, showed no symptoms or signs of disease, but on May 22 she developed so mild an attack that I was not called to see her. The worst case was of a woman aged 29 who developed the jaundice on Feb. 24 after her child aged 4 had had it on Feb. 1. I saw one child of 10 on Feb. 16: she had epistaxis on Feb. 20 and 22, and jaundice developed on Feb. 22. Her younger sister, aged 8, showed both reflexes mildly on Feb. 22, but they were not present 10 days later, and she had had no gastric symptoms. Their small brother, aged 5, on Feb. 22 showed a reflex over the appendicular region, but this seemed completely gone a few days later.

Thus this small epidemic suggests that this combined appendicular and left paramedian reflex has definite diagnostic value in that it enabled me to forecast the appearance of an epidemic before any cases of actual jaundice had been seen, that several times cases were correctly diagnosed before jaundice developed, while in the few cases in which the reflex passed off without actual jaundice or even symptoms there was a strong probability that they were actually mild or symptomless infections. If further investigation should confirm the general validity of these observations, it would give us much-needed help in discovering causes and elucidating the disease. I would, however, repeat what I said in my first letter—that when dealing with children gentleness and tact are needed if the results are to be reliable.—I am, etc.

Winstford, Cheshire.

W. N. LEAK.

### A Diagnostic Sign in Catarrhal Jaundice

SIR.—In connexion with your leading article of Nov. 27 (p. 680) on epidemic hepatitis and the interest being shown in the subject, there are, as you say, many unsolved problems. One great help in solving these would be some clinical means of distinguishing this type of hepatitis from ordinary catarrhal jaundice before the occurrence of many cases makes the diagnosis plain, and also, if possible, some way of recognizing mild and abortive cases. So far serological tests have not been helpful and they always take time. I think there is definite diagnostic value in two points which I have not seen mentioned in the literature, but which have been observed in most of my patients, as also in those of my partner, Dr. Mary MacLaren. The first is the type of vomiting. This comes on suddenly, very frequently at night, and with so little warning that the gastric contents are frequently vomited on to the bedclothes, even in adult cases. This suggests that it is central rather than gastric in origin, and it usually occurs a few days before the jaundice. The latter, as has been noted, often affects the skin before the conjunctivae, and in an early or mild case it shows best on the nape of the neck; in fact the neck looks at first as if it had not been washed, and the jaundice may spread no further. This is, I think, very typical.

A sign which is more definite than these two symptoms is the curious Ligat's reflex to which I drew attention in a letter in the *Journal* in 1938 (Sept. 24, p. 683). Briefly the sign is the presence of Ligat's reflex (hyperaesthesia to light pinching of the skin) in the appendix area and also in a definite narrow line about the position of a paramedian incision, to the left of the midline and commencing at the level of the umbilicus. A small epidemic here this year enabled me to test its diagnostic value. I was called on Jan. 8 to see a boy aged 6 for an attack of sickness. On examination I found Ligat's reflex very active over the appendix and also in the paramedian line I have described. I told his mother that the lad would develop jaundice—of which he then showed no trace, nor did I know of any cases in the district—and that probably his two elder brothers would do the same. He duly developed jaundice on Jan. 11, and had a moderately mild attack. On Jan. 19 one brother, aged 9, had an attack of vomiting, and both Ligat's reflexes were present, but by Jan. 26 the sickness had ceased, though the reflexes were still active. On Jan. 31 his elder

### Treatment of Sciatica

SIR.—In the article on pain in the distribution of the sciatic nerve (Dec. 18, p. 773) there is no mention of the French method of treatment. This was published some two or three years after the last war: I think in the *Praticien*. The description was to the effect that if a patient with sciatica lies on his back, well relaxed, with the knees bent over a large firm pillow and presses firmly on a vertical bedboard with the ball of the foot of the affected side, the pain will very likely disappear. The ankle should be dorsiflexed. This method is most efficient, and, as in so many cases of nerve pain, once a few seconds of physiological as distinct from drug relief is obtained the result tends to be permanent. Presumably the explanation lies in the antagonistic innervation (Golla) relaxing the hamstring and leg muscles and so resting the nerve. This explanation was not given in the description.

Contrary to the quoted statement, I remember seeing some three much-inflamed sciatic nerves exposed to view by my late chief, Sir D'Arcy Power.—I am, etc.,

London, W.1.

G. H. COLT.

### Diagnosis of Spontaneous Hypoglycaemia

SIR.—I agree with Dr. R. D. Lawrence (Dec. 11, p. 760) in his view that the diagnosis of spontaneous hypoglycaemia is becoming too popular and overdone as an explanation for minor indispositions. The disease hyperinsulinism is, of course, the clinical opposite of diabetes mellitus, and frequently is curable, if not by dietary adjustments by surgical intervention. But episodes of hypoglycaemia do not necessarily mean excessive insulin. Just as hyperglycaemia is merely a symptom, so hypoglycaemia is a symptom which is encountered in a number of abnormal states other than those of pancreatic origin. The least common of these are gross disorders of the liver (hepatic atrophy provoked by poisoning and causing hypoglycaemia as a terminal event), diseases of the muscles such as progressive muscular atrophy and muscular dystrophy, and abnormalities of other glands of internal secretion such as hypofunction of the adrenal cortex in Addison's disease, hypothyroidism, and insufficient function of the anterior lobe of the pituitary gland (chromophobe tumours). Rather more common is the symptomatic hypoglycaemia occurring not infrequently as a presenting feature in the various psycho-

neuroses. This is sometimes referred to as the nervous type of hypoglycaemia, and is easily diagnosed, for the patient, besides being emotionally unstable and complaining of hunger and weakness before meals, also has other symptoms, not uncommonly those of an anxiety state. The treatment, of course, is simple reassurance and encouragement together with carbohydrate food to overcome the hunger and weakness. Another real syndrome is effort hypoglycaemia, which may arise after strenuous physical exertion. Athletes compensate for this before competitive sports by eating lump sugar.

The term hyperinsulinism should be reserved for those cases of hypoglycaemia in which an adenoma or carcinoma of the islet cells is present or for those few cases in which there is primary overactivity of non-neoplastic insular tissue.

The criteria for the diagnosis of spontaneous hypoglycaemia may be enumerated as follows: (1) a post-absorptive blood sugar (b.s.) value of less than 0.060 g. per 100 c.cm.; (2) intolerance of going long periods without food; (3) symptomatic attacks of hypoglycaemia occurring when the patient is fasting; and (4) relief of such attacks by the administration of sugar. A useful diagnostic point is the previous health of the patient. In all cases of neoplasms of the pancreas the patient enjoys normal health prior to the first hypoglycaemic attack, which usually occurs no more than a few months before the patient seeks medical advice, and subsequent attacks follow with increasing frequency. This course is not seen in the hypoglycaemia of psychoneurotics, and a b.s. in the morning after a night's fast is invariably greater than 0.070 g. per 100 c.cm., whereas in cases of true hyperinsulinism the post-absorptive b.s. value is always less than 0.060 g. per 100 c.cm. Also psychoneurotics who present with hypoglycaemia stand up well to fasting.

All patients who are suspected of true hyperinsulinism should be subjected to the "fast test," which comprises the withholding of all food for about 36 hours with the patient under supervision, preferably in hospital, and when symptoms appear a b.s. is taken and sugar administered to restore the patient's well-being. Such a test reveals all cases of true hyperinsulinism, and very low b.s. values are obtained. Psychoneurotics tolerate the test quite well, and the level of the b.s. is generally as high at the end of the 36-hour period as it was at the beginning. In hyperinsulinism, of course, the development of symptoms necessitates termination of the test many hours before the scheduled period, and the b.s. then is less than 0.050 g. per 100 c.cm.

The mere fact that symptoms are relieved by giving sugar should be interpreted with extreme caution. The level of the b.s. should be ascertained at the exact time symptoms are present, and only with this precaution can the inference be made that any symptom is at all related to the level of the b.s.

Though the medical profession is to-day more than ever "hypoglycaemic-conscious," it is as well to bear in mind some of the more common disorders with which spontaneous hypoglycaemia may be confused: peptic ulcer and functional dyspepsia (spells of fatigue plus hunger relieved by food); attacks of unconsciousness from any cause with or without convulsions; epilepsy itself; intoxication from alcohol; psychotic conditions; the psychoneuroses (hysteria and anxiety states chiefly); confusional states; and all organic diseases in which mental or nervous abnormalities occur.—I am, etc.,

GEORGE R. W. N. LUNTZ,  
Medical Officer, Guy's Unit, E.M.S. Hospital.

### Diet and Peptic Ulcer

SIR.—In his letter to the *Journal* of Dec. 4 (p. 725) Sir Arthur Hurst makes a statement which, because it is based on a life-time study of alimentary disorders and a wealth of clinical experience, lays it all the more open to timely criticism. He shows no sympathy for Dr. Wrathall Rowe's assertion (Nov. 13, p. 619) that meat leads to a far more abundant secretion of HCl in his (Dr. Rowe's) stomach than cheese, and goes on to state, "If it is subjective, and not the result of comparative test-meals, it is valueless"! I, on the contrary, as a fellow-sufferer can both appreciate and sympathize with Dr. Rowe's assertion.

I can well believe that acutely painful experience tells Dr. Rowe when he is secreting abundant HCl, and that he has no need to resort to comparative test-meals for confirma-

tion. Would Sir Arthur have us believe that the secretion of HCl quantitatively, as influenced by the ingestion of different kinds of food, cannot be recognized subjectively by the medical man who, in addition to his clinical training, is also a victim of confirmed peptic ulceration? I hope not.

It is interesting to note that among his patients Sir Arthur has had several doctors who "for years had taken alkalis and belladonna for acidity, till a test-meal showed that they really had achlorhydria." I can only conclude that these doctors never had occasion to resort to vomiting in an effort to relieve their pain. Had they done so they would soon have known whether or not they were suffering from acidity. Would it not be more accurate to say, "Numerous investigations have shown that anything less than 1/100 gr. (hyoscyamine or atropine) has no demonstrable action on the secretory or motor activity of the stomach"?

Sir Arthur Hurst's impersonal, coldly scientific approach to the whole subject is mildly resented by both my hyperchlorhydric stomach and my duodenal ulcer.—I am, etc.,

E. MAURICE WEBSTER.

### Therapeutic Fallacies

SIR,—None of the correspondents taking part in the discussion seems to have sufficiently acknowledged the main issue of the article by Linnell and Thomson. Their criticisms are on minor points, and even there the views of the authors appear to be misrepresented in many instances.

In my opinion the paper is a very courageous attempt to apply to the question of medical treatment the same strict rules as to medical diagnosis. Treatment must be built on scientific principles, developed logically, and proved experimentally; if there are forms of treatment instituted by tradition and habit only, they have to be carefully examined and sifted by the scientific method. Should they "be proved to be valueless they should be discarded" (Linnell and Thomson). Now the Vienna medical school (when such a school still existed) had men with ideas very similar to those propounded by the authors. I cannot help quoting two important witnesses for this statement.

Prof. M. Neuburger, the last medico-historian of the school, writes in his book *British Medicine and the Vienna School* (Heinemann, London, 1943, p. 55): "The therapeutic scepticism of Skoda: The high standard which was reached in physical diagnosis enabled Skoda to follow the course of diseases independently of the subjective symptoms, and he used this . . . to throw light on the value of methods of treatment used by his contemporaries. The worthlessness of many therapeutic measures in common use was thereby revealed, and so Skoda gradually reduced them to a minimum." J. Bauer, one of the younger representatives of the last Vienna school, is a disciple of Mannaberg (and thus indirectly of Nothnagel), of Obersteiner, Wagner-Jauregg, and a junior contemporary of Wenckebach, Chvostek, Ortner, and H. H. Meyer. He is now professor of clinical medicine in Los Angeles, California. In his book *Constitution and Disease* (Heinemann, London, 1942), reviewed in a leading article in the *Journal* of April 24, 1943 (p. 510), he writes in the chapter on "Principles of Treatment" (p. 186): "The physician carrying out a treatment must know as much as possible about the aetiology, pathogenesis, and consequences of a pathologic state that he is about to treat. Otherwise he deserves the title of quack rather than doctor. There cannot be any discussion about this point." Under the heading "Pitfalls and Errors" in the same chapter he criticizes the thoughtless application of vitamin therapy. He discusses at some length the errors that "occur through misjudgment of the nature and prognosis of essential hypertension, chiefly a constitutional disease." He then comments on the many pitfalls and errors occurring in endocrine therapy, his special field of study. He shows how ignorance or even incomplete knowledge, not only of the actions of different hormones but of small and large doses of the same hormone, may cause lasting harm. He concludes this chapter and his book with the following words: "We should be modest and more reluctant to interfere with the precise mechanism of the living machine without necessity. One of the most difficult tasks in medicine is *primum non nocere*!"

These sentences could have been used as motto by Linnell and Thomson for their article.—I am, etc.,

London, S.W.3. V. C. MEDVEI, M.D.Vienna, M.R.C.P.

## Possible Developments in Social Medicine

SIR—Excuse the personal note in this letter, but I wish, as one who has been interested in this subject for forty years, to thank Dr. Pemberton for his contribution (Dec. 11, p. 754): it is very encouraging. Don't let us be too timid, however, or we may fail the democracy we hope to serve. Prof. Ryle, in his admirable address, says that social medicine has nothing to do with politics, and here we tread on difficult ground. Party politics, yes; politics in the great sense of production of good citizens, no. Human values must come first every time: they are easily the "first priority."

Just one illustration of our dilemma. Plans are prepared for large ten-story flats to house families as well as other people. In other ways the plans are excellent and a great advance on pre-existing chaos, but in this one respect the human element has been subordinated to other considerations. Are we to keep silent? Mass flats will tend to produce the mass mind and stifle that tendency to variety upon which progress depends. No social worker will advocate flats for family life. It is a monstrous injustice to children, born and unborn. Some day, perhaps, social medicine will find a voice to pronounce firmly on these human affairs, and a blessed day it will be.—I am, etc.

NORMAN MACFADYEN.

Leeds, W. 10

## Wartime Appointments of Radiologists

SIR—The president and council of the British Institute of Radiology have recently had the opportunity to ascertain the feelings and views of a large number of radiologists who are at present serving with His Majesty's Forces overseas. These officers have, in many cases, been serving abroad for some years, and feel that they may not for some time be in a position to put forward their views or to maintain touch with those bodies by whom radiological appointments may be made during and immediately after the war. Considerable anxiety is felt by many officers that their interests may not be adequately considered, and that their position on return to civilian life may thereby suffer.

I am therefore instructed by the president and council of this Institute to bring these facts to the notice of consultative and appointing bodies for their information. The following suggestions are also put forward, and it is felt that their adoption would do much to relieve the very natural anxiety of radiologists, especially the younger radiologists, now serving overseas.

It is suggested that: (1) No radiological appointment be made for a longer period than the duration of hostilities. (2) Appointments made during the war, whether to British or alien nationals, be, where possible, made subject to review after demobilization has taken place. (3) Such conditions of appointment, if in force, should be clearly brought to the notice of applicants by the terms of the advertisement or otherwise.—I am, etc.,

HUGH DAVIES, D.M., D.M.R.E.,  
Hon. Med. Secretary,  
British Institute of Radiology.

## Artificial Insemination: Moral and Aesthetic Factors

SIR—Some recent correspondence in your columns must suggest to not a few of our profession that if we are to be worthy of the name of doctors—teachers—it behoves us to beware that what we teach is for the welfare of the community. There appear to be some who are prepared in certain circumstances to advocate extramarital artificial insemination. Such stances, however well-intentioned, may nevertheless be misguided. It is well to remember the old saying that hard cases make bad law, and before we accept such procedures as aesthetically and morally justifiable we should pause to consider their implications not only to individuals but to the community in general. If moral and aesthetic standards be loosened and "medical reasons" for this or that procedure become stretched to a point of infinite elasticity, then *facilis descensus Averno*.

There may be some who would say that medicine has no concern with morality, but is not medicine concerned with the general welfare? Morality signifies those standards of conduct which human experience down the ages has shown

to be desirable for the healthy functioning of human society, and herein sexual relationships are a fundamental issue. The begetting, bearing, and rearing of children involve moral and spiritual factors which cannot be ignored without detriment to the welfare of the community.—I am, etc.,

Birmingham

J. R. A. TODHUNTER.

## Medicine and Dentistry

SIR—I was much interested in the letter of Dr. L. Michaelis on dentistry as a specialty of medicine. The modern dentist, trained along with his medical colleagues, must be well versed in the art and knowledge of medical science, being fully conversant with all pathological manifestations in the mouth, whether of local or systemic origin. He must be aware of all general conditions which can be caused by oral sepsis, and in this matter assist in prophylactic medicine by educating the people on the essential factor of oral hygiene.

In 1919 Dr. A. C. Fones of America presented a report of the findings of a five-year demonstration in educational and preventive dentistry carried out in all the public schools of Bridgeport, Conn. (*Dental Cosmos*, 1919, 61, No. 7.) The scheme consisted of educating the school children in the correct method of oral hygiene and in its importance. A number of dental nurses were employed to see the plan was put into effect: they scaled and polished teeth, reporting all those needing further attention. There was a large reduction in the incidence of caries. Out of the death rates from all causes, he gives records of three diseases which are common among children—namely, diphtheria, measles, and scarlet fever. The following figures are a percentage based on 100,000 population:

	1914	1918
Diphtheria	36.6%	18.7%
Measles	20.0%	4.1%
Scarlet fever	14.1%	0.5%

During the great influenza scourge the deaths were only 5.2% per 1,000 population, the lowest on record in cities approaching the size of Bridgeport, Conn. Fones says: "When these various pernicious mouth conditions are more fully understood as the greatest factor in producing disease, medicine will acknowledge dentistry as a specialty. Also from the prophylactic standpoint, mouth hygiene will be considered the most important branch of general hygiene."

Although we lack more proof of the nature afforded by work of this kind, is it not reasonable to subscribe to the thesis that oral sepsis, apart from the question of focal infection, so reduces the resistance of the alimentary tract, respiratory system, and sinuses as to render them more susceptible to infection?

I think it will be agreed that dentistry has no small part to play in the nation's health services, and that it is in the interests of the medical profession to have an adequate dental service. Many outlived drawbacks of and prejudices against dentistry still exist, and this is reflected in the recent fall-off in the number of entrants into the dental schools. Unless adequate steps are taken, in ten years' time such an adequate service will not be possible. While the onus of raising the status of the dental profession and of ousting all these prejudices primarily rests on the shoulders of that profession, much can be done by those medically qualified by helping to educate not only the children but the masses of the public on the importance of oral hygiene.—I am, etc.,

D. JACKSON, B.D.S., L.D.S.,  
Resident Dental House-surgeon, Manchester  
Royal Infirmary.

## Pre-Nazi Medicine in Vienna

SIR—In reply to Dr. Alan Maberly's letter (Nov. 20, p. 661) I would like to make the following observations. I rather feel that your correspondent's criticisms of the medical services in Austria were not altogether fair. In the first place there was no State Medical Service in Austria, but rather an extended panel service, as suggested by the B.M.A. for this country. The hospitals, it is true, were mainly State or municipal, but this is common to most of Europe outside Great Britain. That this service was imperfect goes without saying, but there is no evidence that these imperfections were due to an excess of public control. The charge of inhumanity was not one I heard more often there than one does here. Moreover, the standards demanded by the patient, at least in Vienna, were high, as instanced by the fact that no doctor could get on the "panel" without having done at least two years in a hospital. The patients would no more have tolerated being "Number 793" (they had, and used, the right of complaint to the panel committee) than they would have tolerated a general practitioner

with "two entrances" to his surgery! Far be it from me to criticize the medical services in this country, for which I have the highest respect and with which it is difficult to compare a poor Central European country like Austria. However, it is worth while remembering that the part of the health services the Viennese was most proud of, and which he so often showed off to the admiring visitor, was the public health services run by the City of Vienna, as instanced by the fine tuberculosis and child welfare services, etc.—I am, etc.,

West Didsbury, Manchester. HERBERT E. BACH, M.D. Vienna.

\* \* This correspondence is now closed.—ED., B.M.J.

### Postgraduate Courses for Service Doctors

SIR,—There have been many letters which you have been good enough to print in your columns from Service medical officers about postgraduate courses after the war, with which many of us are in complete agreement. I think this is a very important matter which ought to be emphasized. Many of us would, before war broke out, have liked to take higher degrees or diplomas, but at the call of the Services have had to give up these ideas and also our jobs or practices, and in the case of married men our homes and families, and have made great sacrifices. We do not know what the future holds. In contrast to this, many young men in the Emergency Medical Services are sitting comparatively pretty and taking higher diplomas. We hear of young people taking the M.R.C.P. six or twelve months after qualifying. These are the people who will have all the advantages in the post-war medical world. It seems that this is unfair and needs investigation, for it may cause bad feeling afterwards.—I am, etc.,

S.M.O.

## Obituary

### J. SWIFT JOLY, M.D., F.R.C.S.

Mr. John Swift Joly, senior surgeon to St. Peter's Hospital for Stone, died at his home in London on Dec. 14 after a short illness. This came as very sad news to a large circle of patients and friends, for he occupied a leading position among urological consultants. He rose to this position owing partly to his outstanding scholarship and surgical skill and partly to his genial personality. He had the rare gift of making strangers feel themselves to be in the presence of a distinguished man and yet to feel at ease and at home. He was a good conversationalist, with a spice of Irish wit, and when he expressed his opinion on any controversial question his judgment always had the flavour of originality. In questions related to his own specialty his opinion was received with exceptional respect, almost with reverence. He had many quaint mannerisms which endeared him to those who had the privilege of knowing him well. For instance, he often signed his letters "Yours in haste," yet he never seemed to be in a hurry, but was willing to give time and attention to anyone who sought his aid, and he always gave generously, radiating confidence and tranquillity.

Swift Joly followed Sir John Thomson-Walker as senior surgeon to St. Peter's Hospital and seemed also to succeed him in his unique position among urological surgeons. In this circle he will, of course, be long remembered for his profound knowledge of every aspect of calculous disease of the urinary organs. His massive book on this subject was published in 1929 and became at once the authoritative work of reference. His skill and reputation as a urological surgeon brought visitors from all parts of the world to see him at work in the operating theatre at St. Peter's Hospital or to learn from him in the out-patient department. Whoever the visitor might be, renowned or obscure, he was assured of a courteous welcome. Many of Swift Joly's patients will feel that there is no one who can take his place and no one who can inspire quite the same confidence. His loss will be deeply mourned by all his patients—hospital and private alike—but even more, perhaps, by his professional colleagues, especially those who worked with him at St. Peter's Hospital. He took a personal interest in every detail of administration. He was the one to whom all could turn for advice, and he came to be loved and respected by all who worked at the hospital in any capacity.

John Swift Joly was born at Athlone in 1876, being the youngest son of the rector, the Rev. John Swift Joly. He studied medicine at Trinity College, Dublin, winning many prizes and scholarships, and graduated M.D. in 1902. Before taking the F.R.C.S. Eng. in 1907 he studied abroad at Berne and Vienna. After his appointment as assistant surgeon at St. Peter's Hospital for Stone he confined his practice to urological surgery and soon began the study of the pathology of calculous disease of the urinary tract, which was the subject of his presidential address to the Section of Urology of the Royal Society of Medicine and the theme of his book *Stone and Calculous Diseases of the Urinary Organs* (1929). During the war of 1914-18 he served in Egypt and Palestine as a major in the R.A.M.C., and was later appointed consulting urologist to the Navy. He always took a keen interest in the work of urological surgeons in other European countries and in America, and he was a corresponding member of the American, French, and Italian urological societies, and was delegate for Great Britain to the Société Internationale d'Urologie. For a time he acted as English secretary of the International Association of Urology and was always keenly interested in its activities.

Mr. Swift Joly lived and practised at 80, Harley Street, and it was there that his wife nursed him almost single-handed during his last illness. His son, at present a surgeon in the Navy, was able to visit him a few days before his death. The funeral was at Golders Green Crematorium on Dec. 16. It was Joly's wish that this should not be a public function, and the company consisted almost only of his colleagues from St. Peter's Hospital.

CUTHBERT DUKES.

### SIR ARTHUR HORN, C.M.G., M.D.

We regret to announce the death on Dec. 19 of Sir Arthur Edwin Horn, consulting physician to the Colonial Office and to the Crown Agents for the Colonies, at the age of 73.

A son of William Horn of Forest Hill, he was educated at the City of Westminster School and St. Mary's Hospital. He graduated B.Sc. Lond. (with honours) in 1896, M.B. in 1899, and M.D. in 1906; and obtained the D.T.M. of Cambridge in 1907 and the M.R.C.P. diploma in 1919. During the South African War he was a civilian surgeon attached to the Field Force. He joined the West African Medical Service in 1904 and served on the Gold Coast, in North and South Nigeria, and in Gambia, and received the thanks of the Secretary of State for the Colonies for his report on cerebrospinal fever in the Northern Territory of the Gold Coast (1908), and for his report on sleeping sickness in the Volta River District of the Gold Coast (1910). He was seconded for special service in 1910-12 and was appointed personal assistant to the Principal Medical Officer, Nigeria, in 1913. His next post was that of senior M.O. and member of the Executive and Legislative Council of Gambia. In 1920 he was attached to the Rockefeller Commission for Investigating Yellow Fever, and in the following year he became Director of Medical and Sanitary Services for Malaya. He was appointed medical secretary of the Colonial Advisory Medical and Sanitary Commission of the Colonial Office in 1923. Two years later he succeeded Sir William Prout as medical adviser to the Colonial Office, and in 1928 became consulting physician. He was created C.M.G. in 1922 and received a knighthood in 1937.

Sir Arthur Horn joined the British Medical Association in 1902; he was president of the 5th Congress of the Far East Association for Tropical Medicine in 1923. In addition to his official reports he contributed papers to the *Lancet* on the health of Europeans in West and in East Africa.

CHARLES FRANCIS FENTON died on Nov. 5 as the result of a street accident. He was born on Oct. 26, 1863, and educated at Brentwood Grammar School. At the age of 17 he was apprenticed to a tea-taster in Mincing Lane, but in 1882 became a student at the London Hospital. He qualified M.R.C.S., L.R.C.P. in 1886. He was a dresser to Sir Frederick Treves, contemporary with such people as F. J. Smith and young Jonathan Hutchinson (son of Sir Jonathan Hutchinson, the investigator of syphilis, whose name remains in "Hutchinson's teeth"). He went to Barking in 1888, after doing an assistantship at Wivenhoe, Essex, and acted at the same time as a clinical assistant at the London Hospital, and also at Moorfields. In 1896 Dr. Fenton was appointed part-time M.O.H. at Barking, which post he held until 1909, when full-time appointments for medical officers of health were first introduced on a national scale. While in charge of the first isolation hospital in Barking he was one of the first to use antidiaphtheric toxin in the area. He was of the old type of general practitioner, the true

family doctor who not only advised from a medical point of view but was the family adviser and friend also. Dr. Fenton was in practice in Barking for 55 years.—H. C. B.

Dr. JOHN ROBERT WILLIAMS of Penmaenmawr, J.P. for Caernarvonshire and at one time High Sheriff of the county, died in a nursing home on Dec. 15, aged 81. He studied medicine at the University of Edinburgh, taking the M.B. and C.M. degrees in 1890, and afterwards attended hospitals in London and Paris; he was then for a time demonstrator of anatomy at the Royal College of Surgeons of Edinburgh. For well over twenty years he held the posts of surgeon in the Penmaenmawr and Welsh Granite Quarries and visiting physician to the Manchester and Salford convalescent homes. Dr. J. R. Williams was a keen officer of the R.A.M.C.(T.F.), attaining the rank of major and being awarded the Territorial Decoration; in the last war he served over-seas with the 6th Battalion Welch Fusiliers. In 1922 he was appointed a Knight of Grace of the Order of St. John of Jerusalem in England. He joined the B.M.A. in 1899 and held office as president of the North Wales Branch in 1927-8. He was also a Fellow of the Physical Society and of the Royal Meteorological Society, and being a skilled draughtsman illustrated a number of medical and anatomical works. Until old age claimed him he enjoyed a day's shooting or sailing, and had long been a member of the Royal Welsh Yacht Club.

## Medical Notes in Parliament

### The Education Bill

The text of the new Education Bill, which when enacted will supersede all existing Education Acts, has now been issued. The Bill is based on the White Paper published last July (*Journal*, Sept. 4, p. 304), and includes all the legislative changes proposed in that paper.

### Training and Resettlement of Disabled Persons

Mr. TOMLINSON on Dec. 10 moved the second reading of the Disabled Persons (Employment) Bill. He said the report of the Interdepartmental Committee on the Rehabilitation and Resettlement of Disabled Persons, presented to the House in January, 1943, attempted for the first time to treat rehabilitation and resettlement as a single problem and a continuous process. It was felt that medical science and industrial experience might be complementary to one another. To let a patient know in hospital, soon after his accident and in the presence of his medical adviser, that someone was ready to assist him to take up his work when better, or to train him in other work, might assist more than anything else in making the skill of the surgeon effective. Whatever the disability and whether incurred in industry or on the battlefield, the first step must be to convince the patient that help was possible. Experience in an interim scheme had taught the value of training for a new occupation wherever the disability prevented return to a previous one. The work of the limb-fitting specialists under the Ministry of Pensions at the centres established for that purpose was beyond praise. Experience at Papworth showed that, with the doctor determining the number of hours the individual should work, such work under supervision aided recovery in many tuberculous cases. It was now part of the Bill to make provision for medical rehabilitation, which came under the comprehensive medical service and was being planned. The Bill dealt with the phases of rehabilitation and resettlement which were necessary in addition to medical treatment. It proposed courses of industrial rehabilitation and vocational training. It also proposed a statutory obligation on employers to assist disabled persons to get employment in the ordinary field of industry and commerce. Special facilities were proposed for those whose disablement unfitted them permanently, or for a substantial period, for ordinary employment. War-disabled persons were covered by the Bill like other disabled persons. In spite of the King's Roll, statutory compulsion to employ was necessary.

Major GATES said that in the Ford factory it had been shown that 88% of the jobs in that factory could be carried out by the disabled. Employers would find that the disabled were the most reliable workpeople and among the least accident and the least sickness prone. Mr. ISAACS recalled that the British Medical Association, in conjunction with the Trade Union Congress, had discussed these problems in 1937. Establishment of rehabilitation centres followed. Sir IAN FRASER said that in the last 30 years the percentage of unemployment among disabled men had never been so high as among the fit. Mr. MESSER was glad that the Bill would apply to persons suffering from congenital deformity.

Replying to the debate Mr. BEVIN said the Bill would dovetail in the new Education Bill. He hoped to set up local advisory committees, including hospital people.

The Bill was read a second time.

### Supply of Penicillin

Mr. CHARLES PEAT, in reply on Dec. 16 to Mr. Craik Henderson and Major Lyons, said arrangements had been made to produce as much penicillin as possible. There was at present only a small quantity. The total supply would for some considerable time be insufficient to meet Service requirements. Limited quantities were being made available, in consultation with the Ministry of Health and the Medical Research Council, for clinical trials. Efforts would also be made, as soon as circumstances permitted, to allocate some supplies for the civilian population, but he could give no indication when they would be generally available.

### Regulation 33B in Operation

Up to June 30, 1943, the latest date for which figures are available, the number of persons who were reported as alleged sources of venereal infection by two or more persons under treatment, which is necessary for the operation of Regulation 33B, was 110, and by the same date 71 of these had been brought under treatment by local authorities. About 220 other persons out of approximately 1,780 in respect of whom only one report reached medical officers of health (and who were not, therefore, subject to action under the Regulation) were induced to undertake treatment when informally approached as a result of the single report.

### Scientific Training and Research

A deputation from the Parliamentary and Scientific Committee was received on Dec. 15 by Mr. Ashley, Sir John Anderson, Sir William Jovitt, and Lord Cherwell. Lord SAMUEL headed the deputation, which asked for more Government encouragement to scientific and technical training after the war. Mr. E. W. SALT suggested an additional grant of £1,000,000 to the universities for research and training. Mr. ATLEE indicated that the Treasury was sympathetically inclined. He said plans for science, both fundamental and applied, were prominent in the thoughts of the Government.

### Recuperation of War Workers

Mr. WILLINK announced on Dec. 16 a scheme to provide treatment under medical supervision for workers showing signs of war strain although not suffering from serious illness. He said that in consultation with the Ministry of Labour he had decided, with the co-operation of the War Organization of the British Red Cross and Order of St. John, to arrange for workers to be admitted to a number of country houses hitherto used by that Organization as auxiliary hospitals but not at present needed for that purpose. The War Organization was now selecting accommodation suitable, geographically and otherwise, for this new use. This was an experiment in a new field of social medicine, and the provision must be on a modest scale in the first instance, as the number of centres available was limited. The intention was that individual workers would be selected by co-operative action on the part of their own doctors, their employers' medical officers, and the medical staff of his Department. The course of treatment, which would normally last for two weeks and sometimes rather longer, would consist of physical exercises, indoor and outdoor occupations, and organized games and excursions, all graded according to the condition of the individuals and conducted on lines as far removed as possible from what was usually called the hospital atmosphere. The object was not only to prevent further impairment of the worker's health but to tone him up, physically and mentally, so that he could return to his normal life with renewed vigour and efficiency.

### Medical Examination of Fitness for Mines

On Dec. 17, on the motion for the Christmas adjournment, Col. LANCASTER opened a discussion on the impending call of young men to the mines. He said recruiting by ballot ignored all the data collected by the Service Departments since the beginning of the war in regard to psychological tests. Medical examinations of these young men by district medical boards must be more searching than those made for recruits for the armed Forces. So far as South Wales was concerned, examination of the lungs would be necessary. In examining entrants for the Forces there was a reasonable expectation that minor deficiencies would be improved by military life. In the case of these young men there would be no safety margin. Within a month or so of their presenting themselves they would be going underground and there would be little opportunity of improvement in the medical condition. If they were not fit

they would be an increasing source of worry to already over-worked managements. If as a result of physical or temperamental disability these men were subsequently found unsuitable for mining they should be boarded out by the same medical board, thus saving the friction caused by this having to be done by the local medical practitioner. Machinery must be installed to get rid at the earliest moment of young men found to be unsuitable. At present in the Midlands area boys going into the pits were examined by the medical practitioners of the district. Mr. SLOAN said he had never known of any medical examination to which youths were put before going down the pit. He agreed that there should be one. Mr. COLEGATE also said he had never known of such examinations in his district. His friends would welcome medical examinations of the boys from mining villages who were recruited into the industry. Such entrants would be fewer if they had the same searching examination as for the drafted entrants.

Mr. BEVIN welcomed the acceptance of the idea of a medical examination. This must be a Government examination and must be carried out so that if a slight defect were found the person examined did not feel the world was at an end for him. The employer should not know the result. This should be a matter between the Board, the State, and the person concerned. It would be wrong to let a boy go into the pit if there was proneness to lung trouble. In the light of the last 30 years he thought there had not been enough research in the mining industry on what should be looked for in a medical examination. In the chemical trades it was found that to let people with certain tendencies go into certain processes meant ill-health and a great economic loss. He thought the mining examinations would result in a stepping-up of medical knowledge. The Government would exercise the greatest care and would try to learn from this experiment as it had done in connexion with the Services and in industry.

#### Scottish Scientific Advisory Committee

The present members of the Scientific Advisory Committee to the Secretary of State for Scotland are Sir John Orr (chairman), Prof. C. H. Browning, Prof. F. A. E. Crew, Prof. I. de Burgh Daly, Sir John Fraser, Prof. D. Murray Lyon, Sir Alex. Macgregor, Prof. T. J. Mackie, Sir Edward Mellanby, and Prof. W. J. Tulloch.

It is a practice of the Committee to delegate special investigations to expert subcommittees to which non-members are co-opted.

## The Services

The following appointments, awards, and mentions in recognition of gallant and distinguished services in Burma and on the Eastern Frontier of India have been announced in the *London Gazette*:

C.B.E. (Military Division).—Col. (Temp.) B. Basu, O.B.E., I.M.S. O.B.E. (Military Division).—Col. (Acting) J. A. Matheson, Col. (Temp.) M. Morris, Major (Temp. Lieut.-Col.) V. J. Perez, R.A.M.C.; Col. (Acting) C. C. Kapila, Major (Temp. Lieut.-Col.) C. F. J. Cropper, I.A.M.C. M.B.E. (Military Division).—Capt. (Acting Majors) G. D. W. Adamson, J. S. Kerss, R.A.M.C.; Capt. J. B. Hurl, J. G. Scott, R.A.M.C.; Major J. F. Shepherd, Capt. (Acting Major) L. S. F. Woodhead, Jemadars (Acting Subadars) (Assistant Surgeons) V. D. Sharma, C. Singh, I.A.M.C.; Assistant Surgeon (British Cadre) 1st Class A. V. Barker, I.M.D. D.S.O.—Major (Temp. Lieut.-Col.) G. R. Marshall, R.A.M.C. I.C.—Capt. N. P. Mahapatra, I.A.M.C. Mentioned in Despatches.—Brig (Temp.) G. D. MacAuley, D.S.O., M.C. (Acting) W. J. Officer, Majors (Temp. Lieut.-Cols.) D. M. Ahern, J. H. (Reserve of Officers), A. N. T. Meneses, R.A.M.C.; Capt. (Acting Lieut.-Col.) F. J. Manning, Capt. (Temp. Majors) J. D. Allan, J. C. Babbage, J. B. Meugh, R. A. O. Leroux, J. McGhie, R.A.M.C.; Capt. P. H. Birks, R. A. Coughlan, T. B. Harrison, W. H. Ashford-Brown, T. A. B. Mason, J. Morrison, H. O'Hara, M. C. A. Waymouth, D. G. C. Whyte, R.A.M.C.; Major-Gen A. C. Munro, C.B., K.H.P., Indian Army; Capt. B. K. Banerjee, I.M.S.; Col. A. C. Taylor, Col. (Temp.) J. E. Ainsley, Majors (Temp. Lieut.-Cols.) J. A. Anderson, J. Duffy, R.A.M.C.; Major (Acting Lieut.-Col.) G. F. Harris, Capt. (Temp. Majors) W. S. Hacon, H. B. T. Holland, D. S. Khatav, I.A.M.C.; Capt. A. E. Stevens, G. Audikesavala, B. Barat, G. V. Faulkner, K. N. Gabbar, C. K. Hasean, G. L. Joshi, M. A. Khan, M. Khan, A. I. Lakshminarayana, D. N. Manikala, A. K. Mukerji, J. L. Roberts, G. Quayle, R. S. Tata, R.A.M.C.; Lieut. (Temp. Capt.) N. R. Danl, N. J. McQueen, Lieut. (Acting Capt.) S. T. Gopalakrishnan, I.A.M.C.; Jemadar M. S. Qureshi, I.A.M.C.

The *London Gazette* has announced the appointment as M.B.E. (Military Division) of Temp. Surg. Lieut. J. R. Ellis, R.N.V.R., for distinguished services in connexion with the operations which led to the capture of Sicily by Allied Forces, and of Temp. Surg. Lieut. A. A. McC. Miller, R.N.V.R., for services to the wounded after an air attack.

#### CASUALTIES IN THE MEDICAL SERVICES

Died on active service.—Capt. M. Evnine, R.A.M.C.  
Died.—War Subs. Capt. N. N. Wilson, R.A.M.C.  
Killed in an aircraft accident in South Africa.—Fl. Lieut. C. F. H. Winney, R.A.F.M.S.

## Universities and Colleges

### UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examination indicated:

*Final M.B., Ch.B., Part III.*—1A. H. Swiithinbank, J. Ainsworth, A. J. Beadel, K. W. Boggis, A. M. Brenner, E. F. B. Cadman, Constance N. Davis, P. S. Dearden, Margaret P. Diamond, E. G. Donovan, J. F. Fergusson, H. Francis, J. Gould, Betty Hargreaves, E. T. Harrison, H. Holden, Winifred L. Hollick, C. A. Hopkins, J. G. P. Jones, J. D. King, J. Langley, V. Letze, A. McPherson, W. E. S. Marshall, J. W. Maybury, Janet B. Mercer, Sheila L. Richardson, J. J. Rivlin, Irene W. Simpson, W. Sircus, C. Taylor, K. J. Thomas, D. W. Townley, Simone J. van Son, J. G. Warbrick, Elsie M. Whitaker, Margaret A. Williams, F. B. Wright. *Passed in Separate Subjects:* P. M. Edis (Surgery, Obstetrics, and Gynaecology), K. B. N. Freeman, A. A. Stone (Medicine, Obstetrics, and Gynaecology), J. E. Hall and Barbara I. Thompson (Medicine and Surgery). *Part I:* H. T. Davenport, Monica Drake, M. M. I. el Haddad, L. Griffiths, B. B. Harrison, Muriel E. St. Pier, W. I. Sanders.

1 Class II Honours and Distinction in Surgery.

### ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the Royal College of Surgeons of Edinburgh, held on Dec. 17, with Prof. R. W. Johnstone, President, in the chair, the following who passed the requisite examinations were admitted Fellows:

A. C. Buchan, M. L. Burman, V. H. J. Davies, J. C. Dundon, G. R. Fiel, T. Fletcher, R. H. Foster, M. D. Hickey, W. D. Lovelock-Jones, W. E. Poller, G. I. Roberts, D. F. Walsh.

## Medical News

The Harben Lectures will be given in the Lecture Hall of the Royal Institute of Public Health and Hygiene, 28, Portland Place W., by Dr. Melville D. Mackenzie, chairman of the Medical Advisory Committee, Inter-Allied Committee for Post-war Requirements, on Jan. 24, 25, and 26 at 3 p.m. Dr. Mackenzie's subject is "A Study of the Potentialities of International Collaboration in Medicine in the Post-war World." Those wishing to be present are asked to notify the Secretary of the Institute. Admission is free.

The Association of Scientific Workers is arranging a film show at the Cambridge Theatre, London, W.C.2, on Sunday, Jan. 30, at 6.30 p.m., in aid of its Stalingrad Hospital Laboratory Fund. The main feature will be "World of Plenty," to be followed by other films of scientific interest. Tickets at 2s. 6d. to 21s. can be obtained from the association at 59, New Oxford Street, W.C.

Some of the aims of the Scientific Film Association, which came into being on Nov. 20, are: To promote the national and international use of the scientific film in order to achieve the widest possible understanding and appreciation of scientific method and outlook; to collect, collate, and distribute information on the scientific film; to publish comprehensive lists of films graded according to merit and suitability for audiences; to establish relations with Government Departments, public bodies, etc., which are in a position to make, use, or circulate scientific films; to organize a panel of scientists to advise film producers on scientific matters; to promote the production and distribution of scientific films; and to encourage the setting up of scientific film societies. The medical member of the council of the association is Mr. McAdam Eccles. Inquiries should be sent to the honorary secretary at 51, Fitzjohn Avenue, London, N.W.3.

The Bernhard Baron Trustees' grant of £30,000 towards the partial completion of the nurses' home of Queen Charlotte's Maternity Hospital is conditional on the work being carried out by the end of 1944, and this means that the hospital must raise the balance of £17,000 required in the next twelve months. Queen Charlotte's has already raised nearly half a million pounds towards completing the largest maternity hospital in the Empire.

The issue of the *Schweizerische Medizinische Wochenschrift* for Sept. 4 is devoted to papers on cancer read on Oct. 11, 1942, at the Swiss National League for the Campaign against Cancer.

The name of the Chartered Society of Massage and Medical Gymnastics has now, by permission of the Privy Council, been changed to the Chartered Society of Physiotherapy.

A Medical Faculty has recently been founded at Salonika, in which 400 students have been registered.

Dr. Leslie G. Housden has succeeded the late Dr. Eric Pritchard as one of the honorary medical advisers of the Save the Children Fund.

Dr. Eugenio A. Galli has been appointed president of the National Department of Hygiene of Argentina.

## EPIDEMIOLOGICAL NOTES

## Influenza

The number of deaths attributed to influenza in the great towns during the seven weeks Nov. 6 to Dec. 18 were 31, 46, 106, 375, 39, 1,148, and 1,115. These numbers would have been slightly higher—by about 9%—if the pre-1940 system of classification of deaths had been retained.

The wave of influenza that has spread over the country and the rapid increase in mortality common in large epidemics have aroused general concern. Noteworthy, also, are the reports of widespread epidemics in the U.S.A. and in Germany. The mortality figures are the only measurable indication we have of incidence. But distracted industrial managers, and, last but not least, the harassed and overburdened general practitioner, tell their own tale. Mortality falls on all classes alike, with the exception that infants under 2 in the lower social class have a higher mortality from influenza than those in the upper classes.

The epidemiology of influenza has been extensively studied, but adequate solutions to many of the problems have yet to be found, and results obtained from one epidemic are not in accordance with those of another. Influenza appears to be independent of climatic and meteorological conditions, for epidemics have occurred throughout the world and have begun at varying periods of the year. Though we have evidence that large influenza epidemics have appeared at intervals for several hundred years, this disease did not appear as a major cause in the classification of deaths in recent times until 1890. In that year 4,523 persons died from influenza, compared with an average of 99 for the ten preceding years. In the two following years—1891 and 1892—16,686 and 15,737 deaths were recorded, and the deaths remained at a high level during the subsequent years. From 1893 to 1917 the annual number of deaths ranged from 3,753 to 16,245. A feature of this period was the seasonal rise to a maximum in the early months of the year, generally from January to March. In June, 1918, the great epidemic began, and of the 112,329 deaths in that year 98,280 occurred in the fourth quarter. The epidemic declined during the winter but rose to a secondary maximum during the spring of 1919, and 44,801 deaths were recorded during that year. The mortality then declined, but remained above the level of the preceding thirty years. During 1920-39 the annual deaths varied from 5,019 to 29,084. The largest epidemics during this period were in 1922, 1927, 1929, and 1933, the number of deaths being respectively 21,498, 22,263, 29,084, and 22,990. In six of the remaining fourteen years the deaths numbered between 10,000 and 20,000. During recent years the seasonal trend has been fairly uniform, the deaths beginning to rise at the end of December or the beginning of January; the maximum occurred between the fourth and eighth weeks during 1937-43.

The present outbreak is in contrast to recent experience. It began about two months earlier than usual and has already reached a higher level than has been recorded since 1937. It is impossible to foretell its course. Previous large outbreaks have been almost symmetrical—a rapid rise to a maximum and an equally rapid fall. An epidemic usually lasts from 10 to 12 weeks. If the present epidemic follows this course it is probable that a secondary rise will occur in the late spring. Secondary epidemics are usually not so symmetrical as the primary epidemic and the peak is not so pronounced, but they persist for a longer period.

So far as is known there has been no large change in the distribution of the age of death, as was the case in the 1918 epidemic. During 1890 to 1917 influenza was chiefly concentrated at ages 55+, but in 1918 the age distribution of mortality underwent a sudden and remarkable change, and affected the younger members (under 35) of the population very much more than those at older ages.

## The Week Ending December 18

The returns of infectious diseases during the week for England and Wales included: scarlet fever 1,936, whooping-cough 1,400, diphtheria 550, measles 416, acute pneumonia 2,593, cerebrospinal fever 64, dysentery 133, paratyphoid 1, typhoid 3. There were 1,115 deaths due to influenza in the great towns.

J. P. Murphy, G. S. Bozalis, and E. J. Bieri (*Amer. J. Dis. Child.*, 1943, 66, 264) studied the blood diastase in 35 cases of mumps of all ages and both sexes with or without complications and at various stages of the disease, and found that in 58 determinations only 7 were below 200. They came to the conclusion that in the overwhelming majority of mumps cases the blood diastase is raised, whereas in cervical adenitis the diastase is low, so that this occurrence is of diagnostic value.

## INFECTIOUS DISEASES AND VITAL STATISTICS

No. 49

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 11.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

\* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

## Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Atiology Westcent*, London; SECRETARY, *Medisecra Westcent*, London. ADVERTISEMENTS, *Articulate Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

### ANY QUESTIONS?

#### Analgesia in Labour

**Q.**—What is the present position regarding analgesia during labour? Are there any risks in the use of scopolamine? What is the dosage recommended, and how early in labour should it be given? Is a rapidly acting barbiturate to be recommended, and if so in what dosage?

**A.**—A few women express a wish to go through labour unassisted by analgesics. Some of them change their views before labour ends. A few doctors claim that with adequate ante-natal preparation a woman does not need sedatives during labour, and encouraging results in small selected series are produced to support their view. The majority of patients and obstetricians believe that analgesia is necessary. If the choice and dosage of drug are wise and the administration timely, pain is relieved, labour is shortened, and is made safer for both mother and babe. Scopolamine gives its best results when used in combination with morphine, but considerable care is necessary if good results are to be obtained and unfortunate sequelae prevented. There should be a nurse adequately trained in obstetrics and in the use of this particular analgesic in constant attendance on the case. The doctor must be prepared to devote even more time than usual to watching the patient during her labour. There must be facilities for nursing the patient in a quiet room, and no sedative should be given, preferably, within 3 hours of the birth of the babe. Even with these precautions blue asphyxia is common, with the added risk for the babe of atelectasis and pulmonary infections. The use of scopolamine (hyoscine) is not free from risk. When first-stage pains become regular and strong 1/6 gr. morphine with 1/150 gr. scopolamine is given. Subsequently, 1/450 gr. is given as required to keep the patient quiet. It should not be repeated more frequently than hourly and should not be given in the second stage. The morphine is not repeated.

The barbiturates are widely used at the present time. One that does not produce the extreme excitement occasionally met with is to be preferred. A good combination is to give this by mouth in combination with morphine or heroin by injection when first-stage pains become strong and regular. In a primigravida 1/6 gr. heroin with 6 gr. hebaral gives excellent results in a normal labour lasting less than 24 hours.

#### Intra-uterine Douche in Puerperium

**Q.**—For some years I have used a copious intra-uterine douche followed by glycerin in puerperal cases with offensive lochia in large subinvolved uteri. This treatment facilitates drainage through an oedematous infected cervix and removes debris retained beyond the reach of eliotherapy. I have found the results consistently good. Fœtor is reduced and there has been no ease of spread of infection. There is little distress to the patient, and quite often dramatic results. An anaesthetic is never necessary. A review of the literature reveals that this practice is universally condemned, but no facts or figures are given to substantiate the condemnation. Wherein have I sinned?

**A.**—Not at all. You have been fortunate. If a uterus is infected and the flow of lochia is obstructed, the correct thing to do is to establish drainage. Gentle flushing with a hot intra-uterine douche is a reasonable and—as you have found—successful method of treatment. If, however, placental tissue is retained, then you are fortunate if you manage to wash it away in this fashion. To leave it is asking for trouble, and the wisest plan if you suspect the presence of retained placental tissue is to explore the uterus gently with the finger or with sponge forceps. To do this properly you will require an anaesthetic, and on occasions the retained tissue is closely attached to the uterine wall. The greatest care is essential if perforation is to be avoided.

#### Vertigo and Vomiting in Middle-aged Women

**Q.**—During the last two years I have had a very large number of patients suffering from vertigo for which I can find no adequate reason. The most severe case was one where feeding was difficult because whenever the head was raised from the pillow the patient vomited every time because the vertigo was so severe. The only constant factor in these cases appears to be that the patients are all women and all over 40. I may add that the majority are transient cases of a few weeks' duration, but some have been more persistent.

**A.**—It is not stated whether any other symptom or sign such as deafness or nystagmus was present, but apparently there was nothing except vomiting. It seems, therefore, not to be due to a unilateral obstruction of the Eustachian tube with labyrinthine disturbance. It might be functional or due to an epidemic of encephalitis. However, women over 40 often drink tea to excess, and this is quite able to produce severe attacks of vertigo with nystagmus and vomiting, but not necessarily deafness.

#### Food-poisoning Outbreak

**Q.**—During August, September, and October there were in a South Devon district a large number of cases of gastro-enteritis. The symptoms are severe prostration, vomiting, and diarrhoea, the latter of an explosive type, coming on suddenly at times and without warning. Colitis is prominent and persists after the gastric symptoms have subsided. The treatment consists of mixtures containing kaolin bismuth, rhei co., and sedatives. In one small village 50% of the inhabitants were stricken down suddenly. Suggestions for the treatment of the colitis would be welcomed.

**A.**—These outbreaks are almost certainly "food-poisoning" in its widest sense. The Salmonella and dysentery organisms are probable causes, the persistent colitis suggesting, more particularly, *B. dysenteriae*. Bacteriological diagnosis must be made before satisfactory treatment can be suggested. The condition, whether true dysentery or non-specific food-poisoning, is compulsorily notifiable to the medical officer of health.

#### What is Fibrositis?

**Q.**—What is the pathological explanation of the dramatically sudden and devastating onset of "fibrositis" in an acute attack of lumbago, whereby an apparently fit individual is converted in a fraction of a second into a helpless and agonized cripple? Why not a gradual onset?

**A.**—In his original description of fibrositis Sir William Gowers considered that the pain originated in the muscle spindles, the end-organs of the afferent nerves which lie between the muscle fibres and in intimate association with them. While it is obviously impossible to demonstrate the manner in which the characteristic pain is evoked, it may be assumed by analogy that it is due to compression of the muscle spindles by spasm of the adjacent muscle fibres, and is thus of a similar nature to the cramps commonly occurring in the muscles of the extremities. While the acute onset is brought about by some movement involving the muscles concerned, there has been a gradual accumulation of toxic products in the tissues leading up to the acute attack—when, so to speak, the pot boils over. Cases with a gradual onset are common enough both in the lumbar muscles and elsewhere, but rarely reach the same intensity of pain; anatomical relations, function, and blood supply all probably have a bearing. It is questionable whether the term fibrositis is not used too freely—sometimes, indeed, as a cloak for ignorance; and myalgia, myositis, fibromyositis might be recognized as varieties in close association in symptomatology. A symposium on fibrositis in its various aspects appeared in the *Annals of the Rheumatic Diseases*, December, 1940, vol. ii, No. 2.

#### A Hungry Diabetic

**Q.**—A potential diabetic, who can keep sugar-free by careful dieting and without insulin, finds his menu is very limited, and hunger is acute at times. Could you name some cereals or flour, or other preparations of a sustaining nature, that might be taken? Can soya flour be baked in loaf form or taken for breakfast as a cereal?

**A.**—If a potential diabetic, who is being carefully dieted, feels hungry he is not having enough to eat. The best treatment is to increase the carbohydrate of the diet sufficiently to satisfy the patient and to give insulin if glycosuria occurs. This treatment will improve his health very much, and he may then be able to give up insulin and still keep the urine sugar-free. If he refuses to have the best treatment, he could eat larger amounts of green vegetables, like cabbage, cauliflower, etc., which contain little carbohydrate, or he could use the so-called "diabetic foods." Some of these contain protein and fat and the minimum of carbohydrate, but many patients do not like their taste. Most so-called "diabetic foods" contain a fair amount of carbohydrate and are pleasant to take, but they may cause a return of the glycosuria. Soya-bean flour can be used for bread and cakes. The sooner a patient of this type starts insulin,

## A LOGICAL DEFENCE AGAINST COMMON COLD

O A logical—and successful—method of preventing the common cold is to stimulate natural powers of resistance by immunising with Cold Dissolved Vaccine (Glaxo). The discomfort and ill health from the common cold is caused by the secondary bacterial infection of the mucosa, and Cold Dissolved Vaccine contains all the bacterial strains commonly responsible.

A course of Cold Dissolved Vaccine (Glaxo) provides protection in many instances, and in others the severity of the attacks is greatly reduced.

## LETTERS, NOTES, ETC.

## Masturbation in Women

Dr. C. J. LODGE PATCH writes from Shrewsbury: I congratulate my colleague on her reply to a general practitioner on the above subject (Sept. 11, p. 349); but the patients to whom she refers are seeking relief because "they feel they are abnormal." Four questions were asked, and they do not seem to be answered dogmatically and unequivocally enough to bring the required relief. (1) *How widespread is this practice?* It is almost universal. Certainly more than 90% of normal women have masturbated at some time or another in their lives. It is commoner in women than in men for a variety of reasons, one being that the habit can be acquired and carried out "innocently." Havelock Ellis quotes the case of a lady of title, the president of a society for the suppression of vice, who discovered to her horror that she had been masturbating all her life without knowing what she had been doing! A practice so widespread can hardly be regarded as abnormal, and an appreciation of this fact should help to relieve the anxiety of the patient. (2) *Can it cause physical harm?* The physician should inquire what his patient does to obtain relief for her state of tension. If she employs the usual methods of titillating the clitoris or labia minora, or of rubbing the edges of the latter together in some way, he can conscientiously assure her that no physical injury will result. Certainly no more than from sexual intercourse. If she introduces foreign bodies into the vagina or (in rare cases) into the urethra, there is a risk of physical injury. It is important to ask what method the patient uses, and not whether she uses an artificial substitute for the male organ. The latter form of interrogation may suggest ideas which would not otherwise occur to the patient. If she has already adopted the latter technique, it will not be difficult to persuade her to discontinue it in favour of less injurious methods of producing the same result—orgasm and a relief of tension. (3) *Can it make normal intercourse less satisfactory?* A patient asks this question because she has already discovered, or has been told by a dissatisfied friend, that masturbation is preferable to marital intercourse. Comparisons are odious, but the underlying assumption is that she obtains complete sexual relief through masturbation, whereas she is left unsatisfied after conjugal union. She will be relieved to know that the fault may lie not with herself but with her husband. It is he (when he returns from over-seas) who may need the advice of a psychiatrist or physician. He may be thoughtless and selfish; he may have neglected the preliminary caresses which are so necessary for a woman before she can obtain complete gratification from the man she loves; or (the most common cause of marital dissatisfaction and nervous disturbance) he may, in good faith, practice coitus interruptus or "withdrawal." (4) *How can they be helped to overcome the habit?* A word of caution is necessary in answering this question. Masturbation is a sedative, and a comparatively harmless sedative, to the normal woman, provided it is practised within reasonable limits. Immediate cessation will certainly increase her sexual tension, and may precipitate nervous symptoms: an illustration of the cure being worse than the disease. If the habit is to be "overcome" it must be done gradually. A frank discussion of the first three questions in language which the patient can understand, and the measures suggested towards the end of the reply on page 349 (to which this letter is merely a supplement) should be sufficient for all normal individuals. In conclusion, I would like to endorse the opinion of my sister psychiatrist, that it is usually the neurotic who seeks advice; and that the neurosis is due not to physical but to mental traumata—feelings of guilt and anxiety, a sense of inferiority, etc.

## Parodontal Disease

Mr. R. V. TAIT, L.D.S. (Rickmansworth) writes: With reference to the question about bleeding gums (Oct. 23, p. 534), I should like to say that bleeding from the gums may be a symptom of gingivitis but is not necessarily a symptom of pyorrhoea alveolaris. Unfortunately there is much looseness in the terminology applied to parodontal diseases, and any case of marginal gingivitis where a purulent discharge can be expressed around the teeth is often described as pyorrhoea. The term "pyorrhoea alveolaris" implies a lesion of the alveolar bone. While a marginal gingivitis of long standing may result in progressive destruction of the alveolus, there are other cases in which the bone loss cannot be traced to any local cause but appears to be a bone dystrophy of obscure origin. It is this latter variety that can be described accurately as pyorrhoea alveolaris, and this is also the variety of parodontal disease for which no satisfactory treatment is known other than extraction of the teeth. In these cases, although pockets may be deep with a marked discharge of pus, marginal gingivitis and bleeding are sometimes remarkably absent. It should be emphasized that parodontal disease arising as a marginal gingivitis from local causes may be treated successfully even when it has caused bone resorption to a marked degree. Many teeth that might be conserved are being extracted because of a misdiagnosis of pyorrhoea alveolaris, when there is really no more than a chronic gingivitis. Gingivitis may

arise from a variety of causes, most of which act as direct irritants to the gum margin. General lack of oral cleanliness, deposits of calculus upon the teeth, ill-designed dentures, or faulty restorative work are among the most frequent causes, but irregularities of occlusion of the teeth play an important part. Treatment essentially falls within the province of the dental surgeon, entailing the correction of local factors exciting the inflammation and the elimination of all pockets, but the success of treatment depends upon the thoroughness with which the patient carries out a simple but precise daily routine of oral hygiene. Mouth washes and vitamin preparations, as are frequently prescribed by physicians, seldom alleviate symptoms, and do nothing to produce a cure because they fail to eradicate the cause.

## Action on Uterus of Antispasmodic Drug

Dr. M. GHOSH (Burton-on-Trent) writes: The following case has convinced me of the antispasmodic action of trasentin on the uterus, which may prove of value in various obstetrical and gynaecological conditions. A nullipara aged 40, with irregular menstrual history, was examined by me at an early stage of pregnancy. She gave a history of three previous pregnancies, ending by abortion between 16 and 20 weeks. I attended her in one about 6 years ago. I put her on a regime of vitamin E, thyroid, and luteal hormone. During what I estimated as the 16th week of pregnancy she had backache, which gradually got worse, and had spasmodic intermittent pain over her lower abdomen, accompanied by visible and palpable uterine contractions. Injection of 1/4 gr. morphine gave some relief of pain but little change in the uterine contraction. After about 12 hours one ampoule of trasentin was injected intramuscularly and two tablets given orally. The relief of pain and spasm was obvious. Another injection was given in 12 hours, and four more tablets orally. Now there was no pain or uterine contraction. Although there were no pain or uterine contractions one injection and 6 tablets were given daily for 3 days. The pregnancy has proceeded uneventfully to full term. She is waiting the onset of labour any day.

## Tropical Bubo

Dr. R. N. HALL (Kano, Nigeria) writes: I was interested in Brig. Stammers's article (May 29, p. 660). We treat large numbers of these cases and find that intravenous injections of *Ducrey bacillus* vaccine are by far the best. The injections are given on alternate days, starting with 250 million bacilli and increasing the dose according to the reaction. Most cases need only three injections. When we are short of vaccine we use intravenous boiled skimmed milk, and have found it more satisfactory than anthiomaline or T.A.B. vaccine. We have not been able to find *Ducrey's bacillus* in the pus from the buboes. Any surgical intervention or local application, other than aspiration, is unnecessary and inadvisable.

## Chemotherapy in Intestinal Infections

Capt. I. S. DALTON, I.M.S., writes: I notice that Dr. Austin CL ("Sulphonamide Chemotherapy of Intestinal Infections," July 1, p. 35) used 2 drachms of sodium sulphate night and morning for his third group of patients. Is not this drug much more effective when given two-hourly or four-hourly? Might not this method of administration have influenced the progress of these patients unfavourably? Twenty days seems rather a long time for cure in cases of "a mild character."

## Treatment of Sciatica

Dr. B. H. SHAW writes from Totnes: I was surprised to note Sir Arthur Hurst's article on "The Treatment of Sciatica" (Dec. 18) that no reference is made to local inductothermy, which I have found very successful even in cases of quite definite traumatic origin. I was under the impression that it was commonly prescribed where the apparatus was available.

## Oedema of Ankles in Hot Climate

Dr. W. WATSON NEWTON writes: On a voyage round Africa as S.M.O. of a troopship I suffered from a simple form of oedema of ankles which was so pronounced and persistent that it was with relief I found there was no albumin in my urine. Off the West Coast for 10 days or so of tropical heat I had no signs and it was only after a week or more of profuse sweating in the Red Sea area that the oedema appeared. My idea is that the condition is due to a change of the saline contents of the blood plasma caused by saline loss through sweating, and appears in the ankles as the most dependent parts of the body, where fluids would most likely gravitate. The oedema was always much improved by the night rest, and disappeared as soon as we reached a cooler climate.

## Correction

The last sentence of Dr. Wilfred Harris's letter on "The Treatment of Facial Palsy" (Dec. 25, p. 828) contained an unfortunate misprint. It should have ended "unless the nerve is decompressed or grafted."

## GUNSHOT WOUNDS OF THE HEAD IN THE ACUTE STAGE\*

BY

HUGH CAIRNS, D.M., F.R.C.S.

*Consultant Neurosurgeon to the Army at Home*

For my address I have chosen the subject of gunshot wounds of the head, with particular reference to surgical treatment in the acute stage. From the outset of the war the Army Medical Services encouraged segregation of head injuries under specialists in neurosurgery and neurology, both at home and abroad; and as a result of this policy information has now been collected which enables us to treat an increasing number of battle casualties with greater understanding and confidence than we possessed at the beginning of this war.

### Neurosurgical Tactics and Dispositions

Our experience is derived mainly from the work of our neurosurgical units in the Middle East and North Africa. The first neurosurgical unit was mobilized early in 1940. Major W. R. Henderson of Leeds and Major John Challis were largely responsible for working out the details of the neurosurgical and anaesthetic equipment respectively with the help of the appropriate branch of the Army Medical Directorate, Lord Nuffield, and Mr. A. R. Bullock of Morris Garages. The neurosurgical unit was not designed to nurse or feed its patients, and did not usually have its own x-ray equipment, but was in all other respects self-contained and able to work at C.C.S. or general hospital. It had its own vehicles, its own source of electric power for diathermy, suction pump, operating-theatre lights, operating-table heaters, and so forth. In an empty building or tent the unit could set up its equipment and be ready to operate within an hour, and it could pack up and move elsewhere in shorter time.

As things turned out, when we first joined battle with the enemy on land the mobile self-contained character of these units fitted the requirements of modern warfare. However, our first unit had been in France for only a few days before the battle began, and there was no time for the usefulness of its mobility to be appreciated. It was captured while in surgical charge of some 800 wounded. In a not dissimilar situation at Benghazi, 18 months later, another neurosurgical unit, under the command of Major P. B. Ascroft, was able to continue work until within a few hours of the Germans' entry and then to make good its escape with all its vehicles and equipment. Later, when we were advancing across Tripolitania and Tunisia the mobility of another unit enabled the late Major K. C. Eden to keep with the forward C.C.S. and to operate on the majority of the head injuries of the Eighth Army within 24 hours.

The original equipment of these units has now stood the test of several campaigns,† and has been to some extent copied in the mobile craniothoracic units of the Emergency Medical Service and the mobile surgical units of the Canadian Army.

\* A review of the work of the Neurosurgical Units of the British Army, being the presidential address to the Section of Neurology of the Royal Society of Medicine.

† In the Tunisian campaign Major Eden added a mobile operating van, built in a captured Italian motor coach (Eden, 1943).

The units have fitted in well with the rest of the Army Medical Services, not making disproportionate demands, and ready to turn their hands, when required, to urgent work outside their special field. However, there have been several alterations in the tactical use of the units. Early experience showed the difficulty of securing segregation of the wounded in the forward area. Both Henderson in France and Ascroft in the Western Desert found that no more than 10% of the wounds they were dealing with were head injuries. It was therefore decided that neurosurgical units should in future not work in advance of general hospitals. This policy was maintained with Major J. Schorstein's unit in North Africa, and at first with Eden's unit in the Middle East—until after the fall of Benghazi at the end of 1942. For Mareth and subsequent battles Eden, with the approval of the D.D.M.S., split his unit, leaving one section with a general hospital in Tripoli, and himself with the other section went forward to the most advanced C.C.S. From Mareth to Tunis the lines of communication were unusually narrow, and the majority of the head injuries passed through his hands (Eden, 1943). What he missed or was too busy to deal with went to the rear section of his unit at Tripoli. In this way Eden's unit dealt with most of the head injuries of the Eighth Army in the battles from Mareth to Tunis, and at an earlier stage than in previous campaigns. Out of 293 head injuries 188 were operated on within the first 24 hours, and only 34 were older than 3 days. The result was that the proportion of primary wound healing which he obtained reached the remarkable figure of 90%.

With the First Army Schorstein was in less favourable circumstances, for his lines of communication were more difficult. However, he has estimated that in the later stages of the Tunisia campaign about 75% of the head wounds of the First Army were passing through his hands. He was unable to retain cases for long, and the subsequent follow-up has not proved as easy as in the longer-established bases of the Eighth Army.

### Results

The results of some of our neurosurgical units are set out in Table I. It is difficult to make comparisons, for there are so many variables—in particular the age of the wound at the time when the wounded man receives expert surgical treatment. But we must attempt to establish some standard, and the results of our different units are in some respects remarkably consistent. From the last war we have Cushing's well-documented series for comparison. From the Eastern Front in this war there are almost no precise figures as yet available to us.

### Non-penetrating Wounds

In non-penetrating wounds—that is to say, wounds of the scalp and skull without penetration of the dura—there is practically no mortality. Ascroft, Eden, and Schorstein between them report 459 non-penetrating head wounds, with 3 deaths. One of these was from severe cerebral contusion; one from

penetration of the lateral sinus by a spicule of bone, followed by septic thrombophlebitis of the lateral sinus and pyaemic abscesses of the lungs; and one from a tear of the internal carotid artery in the carotid canal.\*

Non-penetrating wounds are, to be sure, not wholly free from complications: among the cases from Dunkirk there were two of septic scalp wounds which were followed by intracranial abscess (Cairns, 1941); but if the wound is adequately treated in the initial stages subsequent intracranial infection should be rare.

From time to time since the beginning of the war the need for more careful surgical treatment of scalp wounds has been stressed (McKissock and Browncombe, 1941; Botterell and Jefferson, 1942). I believe that there has been considerable improvement, but both at home and abroad a serious difference still exists between the scalp wounds treated by the general surgeon and those of the neurosurgeon. In the recent campaigns Eden and Schorstein have been able to send their patients with scalp wounds back to duty in 10 to 21 days; but when a stitched scalp wound is suppurating and still contains fragments of dirt and hair which should have been removed at the original operation many weeks must elapse before the soldier is ready for duty again. In the Army, wherever neurosurgeons are available, there is an increasing tendency to send all these cases to them. But there are not enough neurosurgeons to supply all the needs of the Army—or, for that matter, the needs of the civilian population in this respect—and it is abundantly clear that general surgeons, or the new class of accident surgeons, must continue to deal with the majority of the scalp wounds which occur in this country. Technically there is nothing difficult about scalp closure, but, like other techniques, it must be learned. As Jefferson has pointed out, the general surgeon can best learn this at the operating table, handling the tools under the guidance of the neurosurgeon.

#### Penetrating Wounds

Let us now consider the results of treatment of penetrating gunshot wounds (Table I).

TABLE I.—Penetrating Brain Injuries

Surgeon	Total Head Wounds	Penetrating Wounds				Remarks
		Total	Mortality (% in brackets)	Primary Healing (%)	Deaths from Infection (%)	
Ascroft (1943)	516	292	44 (15.0)	67 (fresh) 22 (old)	10.8	Base
Eden (1943)	325	102	24 (23.6)	65.5	3.7	C.C.S.
Schorstein	—	112	15 (13.4)	67.6	Low	Forward base
Sorgo (1942)	—	29	13 (44.8)	—	34.5	—
Cushing (1918)	250	133	60 (45.1)	Ca. 70	36.5	C.C.S.

Ascroft was working at the base, and most of his cases had been operated on in the forward area by general surgeons before they reached him three or more days after being wounded. He was subsequently able to observe their progress or 60 days. The low mortality (15%) is an indication of his distance from the firing line: the nearer the front line the higher the mortality. Major Schorstein reports that of 7 men with head injuries in one battalion only 1 survived more than a few hours. In Ascroft's series a remarkably high percentage of cases developed brain abscess while under his care—75 in 292, or practically one in every four penetrating wounds. In the cases first operated on in the forward area by general surgeons the incidence of subsequent brain abscess was more than twice as high as it was in the cases first operated on by Ascroft's team, even though Ascroft's cases were considerably older at the time of operation than those operated on in the forward area. A similar high incidence of cerebral abscess after penetrating brain wounds has been noted by the Russians, and they, like us, have had encouraging results in treatment. Ascroft

had a mortality rate of 25% in his abscesses. Bakulov (1943) reports that in Russia the mortality for brain abscesses, at a specialized evacuation hospital has been reduced to 16.8%.

In the last war Cushing recorded a high incidence of brain abscess, but his cases differ from Ascroft's, and presumably from the Russian cases, in the fact that the abscess came on much earlier and was quickly followed by fatal meningitis. Thus, in penetrating wounds Cushing's total mortality from infection was 36.5%, whereas Ascroft's is 10.8%.

Eden's cases provide an unselected sample of wounded as seen at the C.C.S. level. Thus, 28% of his cases had wounds in other parts of the body. Of the head wounds two-thirds were non-penetrating and one-third penetrating. For penetrating wounds his operative mortality was 23.6%, and mostly due to the initial brain damage. In Ascroft's series there were 73 consecutive "fresh" brain wounds flown from Alamein to the base within 24 to 48 hours of injury, and in these the operative mortality was 25%—practically the same as Eden's. Eden was able to follow most of his cases for up to three months, and there were only 5 cases of meningitis and 1 case of brain abscess. Schorstein's results have been similar to Eden's, but thus far he has been able to follow the subsequent course of only a small proportion of his cases.

Compared with Ascroft's series this represents a remarkable reduction in the incidence of intracranial infection, which is to be explained by the fact that Eden got his cases at a much earlier stage and before they had been operated on by the general surgeon. The end-results as regards life were not so vastly different, Eden's death rate from intracranial infection among those who survived the initial effects of the brain injury being 3.7%, as compared with Ascroft's 10.8%. But the low incidence of abscess in Eden's series has meant a considerable lightening of the work of the neurosurgeons at the base, and probably a reduction in the incidence of post-traumatic epilepsy, if we may judge from Ascroft's finding of a close correlation between the incidence of wound sepsis and post-traumatic epilepsy.

Eden's cases are closely comparable with Cushing's: both worked at a C.C.S. and received "fresh" cases mostly less than 48 hours old. Eden's cases show a remarkable reduction of fatal post-operative infection—3.7%, as compared with 36.5%. This cannot be wholly explained on the basis of improvements in operative technique, nor probably on the addition of sulphonamides. Eden's work lay in North Africa and Cushing's was in France. The only figures so far available from a European front in this war—those of Sorgo from Germany—show for a series of wounds treated late an incidence of intracranial infection almost as high as Cushing's. There is another difference to be borne in mind as between Eden's and Cushing's cases: Eden was dealing with an unselected series, whereas Cushing's cases were selected from among the more serious of a large number of head wounds.

All the neurosurgeons whose work is given in Table I appear to have a primary healing rate in penetrating injuries of between 60 and 70%. In many instances this estimate is necessarily based on observation of the wound for no more than one week after operation, owing to the difficulty of retaining patients. This test is far from stringent, for many war wounds break down slightly in the second or third week. Ascroft's figure of 22% of primary healing for old cases refers to the behaviour of a group of wounds operated on in the forward area by other surgeons and subsequently observed by him at the base.

We may summarize the results thus far obtained in North Africa in the treatment of penetrating brain injuries as follows: Of the patients reaching the C.C.S. about 20% die from brain damage within the next few days. If the initial operative treatment is not thorough and an expectant policy is subsequently adopted, about one in every four of those who survive to be evacuated develops brain abscess or meningitis. This is not dissimilar from the results obtained in France in the last war, when there was a 1 in 3 incidence of intracranial infection; but with the important difference that in the last war the intracranial infection was rapidly fatal at the C.C.S. and few cases survived long enough to develop brain abscess at the base. Recent neurosurgical work in North Africa has shown that when head cases can be segregated at the C.C.S. level and can there be radically operated on within 24 hours of injury

\* In the battles of Passchendaele in 1917 Cushing dealt with 76 non-penetrating wounds, with 6 deaths. At the C.C.S. at which he was working 50% of the battle casualties with head wounds were passed straight on to the base, and his material was presumably selected from among the more serious cases.

by a fully equipped team of experts trained in the not difficult technique of war neurosurgery, there is a considerable improvement. The result: the complication of brain abscess or other forms of intracranial infection can be almost, though not entirely, eliminated.

In modern warfare, where large forces are involved on a wide front, conditions favouring segregation of wounded in the forward area may not occur often, but the advantages to be gained in the way of improvement of results are at present so great that the most forward neurosurgical unit should be mobile and capable at short notice of sending an operating team to the forward C.C.S. In the future, improvements in chemotherapy and in certain campaigns air evacuation, may diminish the need for head surgery in the forward area; the arrangements are flexible enough to enable our armies to take advantage of such altered circumstances.

### Bacterial Infection

Surprisingly little work has been done in the past on the bacteriology of head wounds. In the Sicilian campaign Major Scott Thomson examined material from 36 of our cases and found that all but one contained bacteria (Cairns, Eden, and Schorstein, 1943). The Russians found in 300 head wounds only 2 which were sterile (Report by a Committee of Soviet Scientists, 1943).

In the 36 Sicilian cases, most of which were 3 to 12 days old, the predominating infective organism was *Staph. aureus*.

TABLE II—Brain Wounds 72 Hours Old and Older at Time of Operation

Surgeon	No. of Cases	Died	Discharged	Present Long-term	Primary Wound Healing	Remarks
Eden, Cairns, Eden, and Schorstein (1943)	23	7	2	6	10	Sulphonamides
Watt (1942)	23	3	2	1	6	Penicillin locally
Watt (1942)	29	13	10	—	—	Dural closure 19 cases > 72 hours old

*Staph. aureus* was found in 23 haemolytic streptococci (always with *Staph. aureus*) in 4, and pneumococci in 1. The other organisms found included *Staph. albus*, coliforms, and clostridia. In the penetrating injuries of this group naked-eye examination at operation, combined with bacteriological examination, showed that the infection most usually began under the scalp or in the temporal muscle and spread inwards to the brain.

Case 1.—Marine P. Penetrating right frontal wound and compound fracture of left tibia three days before. After being wounded he was given 2.5 g. of one of the sulphonamide drugs by mouth seven hours after being wounded both his wounds were excised and sulphanilamide was applied to them. Thereafter he had 3 g. of sulphadiazine intravenously, which was repeated after 12 hours at least two more doses. Three days after being wounded his head wound was reopened at a neurosurgical unit. In the subcutaneous tissue there were isolated streaks of thick yellowish-white pus from which *Staph. aureus* was grown. Elsewhere there was firm healthy-looking clot. When this was removed soft pulped brain tissue containing fragments of bone was found protruding through the hole in the dura. Similar tissue and five bone fragments were sucked out of the brain to a depth of 4 cm. Cultures from the bone yielded *Staph. albus*, *B. coli*, and diphtheroids.

In 11 of our cases from the Sicilian campaign Major Scott Thomson examined bacteriological material from different levels of the wound. Pyogenic organisms were present in 3 cases at all levels of the wound, in 6 cases in the superficial layers only, and in 2 cases in the brain only. At operation pus was found in the superficial layers of the wound, under the scalp, or in the temporal muscle, but not in the brain; in 3 cases both the superficial layers and the brain contained pus.

Additional evidence is provided by the observation that the brain abscess develops usually in those cases in which the wound continues to suppurate, and less commonly in cases in which the skin heals by first intention. Thus, in most cases the infection first develops superficially and then spreads inwards. These observations suggest that early sterilization

of the superficial parts of the wound would considerably reduce the incidence of subsequent intracranial infection.

One outstanding question is whether infections on the European fronts are more intense than those in the Western Desert and North Africa. In limb wounds the incidence of gas gangrene has been considerably less in the Western Desert than it was in France in the last war. In brain wounds in the last war Cushing reported gas infection of the brain, and *B. welchii* was cultivated from brain wounds, but no systematic bacteriological examinations appear to have been made. In this war the Russians have recently reported that a large proportion of deaths from brain wounds are due to pathogenic anaerobes (Report by a Committee of Soviet Scientists, 1943). Now, it is well known that many wounds contaminated with clostridia do not develop gas gangrene. Clostridia are found in brain wounds. But the organisms of gas gangrene require anaerobic conditions in which to multiply and become pathogenic, and on theoretical grounds it is difficult to see how such conditions can be obtained in the brain if at operation the brain wound is cleared of necrotic material. It is rare in head wounds for a large part of the brain to be deprived of its blood supply, as happens not infrequently in a wounded limb. Clinically, the cases described by the Russians as suffering from gas infection of the brain do not differ from what we have seen in fatal brain injuries due to Gram-positive cocci. Gas can occur in brain wounds without gas gangrene. That there has been no gas gangrene of the brain in the Middle East is the view of Major MacLellan, O.C. of a mobile pathological laboratory attached to the Eighth Army, who has investigated personally the majority of the cases of gas gangrene which have occurred in the Western Desert and has also studied some 58 head wounds bacteriologically.

This is an important question, on which further information would be welcome, because the Russians recommend the use of anti-gas-gangrene serum in infected brain wounds, though their views on this question are evidently not unanimous (Kadin, 1943).

### Operative Technique

A preliminary radiograph of the skull is essential, to show the situation and extent of so-driven bone and metal fragments. The technique of operation has been well described by Ascroft, and there is no need to do more than recapitulate the main points, which are: minimal trimming of the scalp edge; thorough removal of dirt, hairs, metal fragments, etc., from the subcutaneous spaces; removal of bone sufficient to expose the dural opening; and thorough removal of clot, pulped brain, hairs, and bone chips from the wound—also any metal which happens to present in the brain wound, but no attempt is made to search for deeply penetrating metal fragments. To removing in-driven bone fragments particular care is necessary when, as shown by radiographs, the bone fragments lie against the medial surface of the cerebral hemisphere or in the neighbourhood of the Sylvian fissure. In these situations dislodgment of a bone fragment may start severe haemorrhage from a cortical artery. When the wound is clean and dry it is dusted with a sulphonamide, and sulphathiazole has been used in some hundreds of brain wounds with no reactions of the kind described by Watt and Alexander (1942) as occurring in uninjured brains. The scalp is closed, as Ascroft puts it, "in the absence of gross sepsis," particular care being taken to avoid undue tension at any one part of the wound, and for this purpose plastic procedures may be necessary.

Eden and Schorstein, if I interpret their work correctly, have concentrated increasingly on the need to obtain firm closure of the wound. They have also dealt in uncompromising fashion with cases already excised and sutured in the forward area. If radiographs still show retained bone chips in the brain—as all too often, unfortunately, is the case—they do not hesitate to re-excite the wound, clean out the brain cavity, and then resuture the wound, a procedure which sometimes entails the most extensive plastic measures.

In certain special situations brain wounds present additional difficulties. Wounds of the sagittal and lateral sinuses may be suspected when radiographs show penetration of the skull or in-driven bone fragments in the neighbourhood of the venous sinuses. The particular danger in these cases is a severe, even uncontrollable, haemorrhage. In such cases blood

transfusion should be quickly available if required, the patient should be operated on with his head raised (there is little or no bleeding from the sagittal sinus in a patient who is sitting up in a dental chair), and removal of the bone around the wound should proceed very cautiously until the blood sinus is exposed.

Wounds involving the eye, the accessory nasal sinuses, and the brain present a special difficulty, inasmuch as it is necessary to repair the dura over the sinuses, as well as to close the scalp wound, in order to seal off the brain cavity. This is an operation of considerable magnitude, involving usually fascia lata grafting of the dura covering the poles and inferior surfaces of one or both frontal lobes. In the acute stage the patient may not be fit enough, or the surgeon may not have time enough, for such a prolonged operation. Schorstein (1943) has recently had considerable success in such cases with vaseline gauze packs after débridement. His results do not bear out Tonnin's gloomy view of the inevitability of meningitis in such cases.

Another variety of case which calls for special treatment is the small, clean, penetrating head wound associated with persisting neurological signs—for example, the parietal wound with contralateral hemiplegia. Such cases are probably best dealt with by an osteoplastic flap which has the wound in its centre, a type of operation which was strongly advocated by the French in 1940 for the majority of brain wounds. In the variety of case which we are now considering the osteoplastic flap is the best means of securing a really adequate exposure of the brain wound and thorough removal of the intracerebral clot which is usually present, sometimes as the result of delayed haemorrhage (late apoplexy). Risks of spreading sepsis of the bone flap are small in such cases, for the wounds of which I am speaking now are usually clean, and the methods of preventing infection by means of bacteriostatic substances are becoming increasingly effective.

#### Chemotherapy

Sulphonamides have been very extensively applied, both locally and parenterally, in the treatment of war wounds, and it is unfortunate that no large-scale experiment as to their value was undertaken before their use became general. At this stage it would be extremely difficult to introduce a controlled experiment. There are good theoretical grounds for believing that sulphonamides effectively diminish streptococcal contamination of fresh wounds, but their action on staphylococci is weak and there is no evidence to support the view that they are active in the presence of pus. The Eighth Army has developed the use of sulphonamides in the forward area to a high level of efficiency, and there were few cases in the Sicilian campaign which had not had sulphonamides locally, and in the severe wounds parenterally as well, by the time they arrived back in Tripoli and Sousse 2 to 12 days after being wounded. Yet practically all these wounds were infected—the majority with Gram-positive pyogens—and a considerable proportion were suppurating. Thus, of 22 brain wounds 3 to 12 days old, 19 were infected with Gram-positive pyogenic organisms and 13 were to the naked eye purulent. Here are some examples:

**Case 2.**—Pte. W. T. Multiple wounds, including penetrating right frontal wound. Six hours later excised and dressed with 10 g. sulphathiazole. Sulphadiazine was given intravenously for the next five days, also 5 g. intraperitoneally on the day after injury, when negative exploration of the abdomen was done in the fear that he was developing peritonitis from one of his wounds. Total sulphadiazine, 23 g. On the eighth day, at Tripoli, there was pus beneath the scalp of the right frontal wound (*Staph. aureus*); the other wounds showed no pus or bacterial growth on culture.

**Case 3.**—Pte. F. S. Left occipital wound. Excised the same day. Dressed with sulphathiazole. Given 34 g. of sulphathiazole by mouth in the next seven days. On the eighth day, when the wound was reopened, free pus was found (*Staph. aureus*).

It might be argued that sulphonamides were given to these patients at irregular intervals and that a good concentration of the drug could not have been maintained. I don't doubt that this is true, but it is questionable whether in the forward area administration of the drug can ever be regular. In the course of his journey back to the forward base the wounded man may go to R.A.P., M.D.S., one or more C.C.S.s, hospital

train, or M.A. convalescent, or hospital ship. In such conditions it is extremely difficult to maintain even regular administration of fluids.

Although large-scale trials of sulphur amides are now practically impossible in war wounds, I think some useful investigation in a small way might still be done with the head wound. It would be impracticable to alter practice in the forward area, but at the head centre, taking all cases less than 24 hours old, alternate cases could be done without any further sulphur amides, and the results compared with those which had further sulphur amides. Experience suggests that there would be a reasonable experiment, and if the results showed a significant difference in the two groups, then the 2-day-off-ferm could be tried, and so on. Such an investigation would at least help to put chemotherapy at the head centres on a rational basis.

#### Penicillin

Experimental and clinical tests have shown that penicillin is a most powerful bacteriostatic agent, preventing the multiplication of staphylococci, streptococci, pneumococci, clostridia and other organisms, and not inactivated by the presence of pus. Given parenterally it does not appear in the cerebrospinal fluid (Abraham *et al.*, 1941), though when the meninges are inflamed traces of it may pass through the blood-brain barrier. With the help of Prof. Florey a trial was therefore made by neurosurgical units at Tripoli and Sousse of penicillin applied locally to brain wounds of the Battle of Sicily. Wounds 3 days old or older were chosen because there was not enough material to do alternate cases, and Eiden's earlier work had shown that the results of operation on recent wounds by current methods were very good. The method employed was to expose and suture the wound as described above. Before the wound was closed a fine rubber tube was led through a stab-hole into the brain cavity and calcium penicillin solution (250 units per ccm) was injected into the cavity twice daily for 4 to 5 days. The average amount used was 15,000 units per case, but in future cases the total dose would probably be smaller. Before each injection the contents of the brain wound were aspirated.

During the battle 25 cases of penetrating brain wound 3 to 12 days old were admitted. On arrival 2 were moribund with large brain fungus; these were not operated on, and the died shortly after admission. Of the 23 wounds 3 to 12 days old, 13 were at the time of operation purulent to the naked eye, some with pus under the scalp or in the temporal muscle; others with pus in the brain and in the superficial layers. Four of the wounds presented a brain fungus. Nineteen of the 22 cases examined were shown to be infected with Gram-positive pyogens. All these wounds—purulent as well as non-purulent—were closed completely, except one in which there was so much skin loss that it was only possible to close part of the wound.

This work will be reported in detail elsewhere (Cairns, Eder and Schorstein, 1943). By regular examination of the aspirated fluid we found that after two days' treatment Gram-positive organisms disappeared in all except 2 cases. One of these was a case of orbito-mastoid wound in which the wound cavity still remained connected with the middle ear and external auditory canal—an open wound, from which the penicillin solution escaped almost as soon as it was instilled. The other was a patient, reported to have *Staph. albus* on the third day in whom subsequently a penicillin-resistant *Staph. aureus* was found. This man was suspected of having an abscess, but no sign of anything developed up to 30 days. In all cases Gram-negatives—*pyocyanus*, *proteus*, and *coli*—persisted usually until the discharge through tube or drainage-hole ceased. If the wounds gaped at any point, as sometimes after a week they did, *Staph. aureus* could occasionally be grown again from the raw surface, but did not appear to interfere with healing.

Three of these 23 patients died—one from an intracerebral clot and the other two from infection. One of these had a severely infected 8-day-old left frontal wound with a brain fungus, and in the left frontal lobe in-driven bone fragments and three different brain abscesses from which pneumococcus was grown. He died of spreading cerebral oedema about 48 hours after operation, and at necropsy still had pneumococci in the abscess wall. Penicillin didn't get a long enough application in this case. Possibly it would have been better to treat him

## GUNSHOT WOUNDS OF THE HEAD

BRITISH  
MEDICAL JOURNAL

37

expectantly for a few days, as the Germans have recommended for brain wounds of this age (Lonnis, 1941), but with the addition of local and parenteral sodium penicillin.

The other case was that of a man with an 8-day-old right frontal wound infected with *Staph. aureus* whose pus became Gram-negative under penicillin treatment (in addition to calcium penicillin, applied locally to the brain wound, he had sodium penicillin, 485,000 units intramuscularly, because of a compound fracture of the femur). This man became drowsy and died on the tenth day after operation; at necropsy an abscess was found in the right frontal lobe which had been incompletely tapped during the last days of his illness. This case is a failure of surgical technique, and it shows the importance of maintaining drainage during penicillin treatment.

Wound healing in the 20 survivors, observed for not less than three weeks in all but 5 cases, was by first intention in 6 cases. In 13 there was a slight gape or sinus in the wound, usually at the site of greatest tension, but most of the wounds healed by first intention. These gapes were usually not serious, for only in one case did a small fungus appear during healing.

These results compare favourably with other series of wounds of similar age (Table II), especially when we consider that more than half of the wounds were purulent and would not hitherto have been sewn up. But the series is small and has not yet been followed up for more than 62 days. Brain abscess might still appear in some.

During the Battle of Sicily the opportunity also presented of treating 17 cases of non-penetrating wounds, 14 to 16 days old, locally with penicillin, usually as a solution, sometimes in powder form. The older cases were heavily infected, with fractures of the skull and bare bone lying at the bottom of a suppurating granulating wound. These wounds and the underlying skull were excised and sutured, and all except two healed satisfactorily, though certain technical mistakes were made at first and temporary sinus formation was not uncommon. In these cases the bacteriological results were not so satisfactory as in the penetrating wounds: in a number the purulent discharge from the sinus continued to show Gram-positive organisms, and these were with one exception cases in which the skull had been fractured. Penicillin is so certain in its effects on Gram-positive cocci, apart from the occasional penicillin-resistant strain, that it is reasonably certain that the solution did not reach all the infected parts. The assumption may be made that there were small foci of osteomyelitis beyond the margin of excised bone. In gunshot wounds exposing and perhaps breaking the skull it is unlikely, when surgical treatment is not immediately available, that good healing will be obtained unless the exposed (and probably infected) bone is very widely excised.

Of penicillin treatment all that we are entitled to say at this stage is that the results are not unpromising. Though penicillin is in great demand and short supply, little is required in the treatment of head cases, and further developments in the technique of its use will be made.

## Summary

The treatment of gunshot wounds of the head by neurosurgical units of the British Army in the Middle East and in North Africa is reported.

Three units treated 459 non-penetrating head injuries (wounds of the scalp and skull with dura intact), with 3 deaths.

There were 506 penetrating brain injuries, with 83 deaths. The variation of mortality in the different series depended largely on the level on the lines of communication at which each unit was working.

In penetrating brain wounds, when the initial debridement was incomplete, about 25% of those who survived the immediate effects of brain injury subsequently developed brain abscess. The onset of intracranial infection occurred later than in the case of the 1914-18 war, and a considerable proportion recovered with further treatment.

At the C.C.S. level 28% of head wounds were complicated by wounds in other parts of the body. Non-penetrating head wounds were twice as common as brain wounds. The mortality for brain wounds was about 25%. In "fresh" cases operated on by neurosurgeons the incidence of post-operative intracranial infection was minimal (3.7%).

Of 36 head wounds 3 to 12 days old all but one were found to contain bacteria. The predominating infecting organism was

*Staph. aureus* (23 cases). Evidence was obtained that in the majority of brain wounds infection develops in the superficial layers of the wound and spreads thence to the deeper layers.

Penicillin was applied locally to a series of 23 brain wounds 72 hours old, or older, with encouraging results.

## BURNS AND SCALDS IN CHILDREN

### AN INVESTIGATION OF THEIR CAUSE AND FIRST-AID TREATMENT

BY

A. W. WILKINSON, F.R.C.S.E.

(From the Royal Hospital for Sick Children, Edinburgh)

In spite of a significant reduction in the gross numbers of deaths from burns and scalds under modern methods of treatment, the mortality rate in young children remains relatively high, even when efficient treatment is provided at an early stage. During the past three and a half years there has been an increase in the incidence of burns and scalds in the Edinburgh district, which has aggravated the coincident reduction in the number of available hospital beds. It has long been recognized that burns and scalds as they affect children are largely domestic accidents, and the most hopeful means of securing a further reduction in the number of deaths is by avoiding those conditions which are known to favour the occurrence of thermal injuries. During the period June 1, 1938, to July 31, 1942, 366 children suffering from burns and scalds were admitted to the Royal Hospital for Sick Children, Edinburgh. This report is based on the information obtained regarding the injuries sustained by these children, and is presented in the hope that interest will thereby be stimulated in the social aspects of the problem of burns and scalds, and that suitable preventive measures will be taken.

## Causal Agent

Table I gives a list of the agents causing the injury, and indicates that these accidents are almost entirely of a domestic nature. The commonest cause was the upsetting of a cup of tea. The average age in this group was 18 months, and usually the child was being nursed on the lap within easy reach of the tea-cup; sometimes the adult was holding both child and cup when the accident occurred. The injury thus produced is characteristic, usually involving 5 to 10% of the body surface, the commonest sites being parts of one side of the face, neck and chest, one shoulder and arm. Similar but more extensive injuries resulted from the upsetting of kettles (59) or teapots (43): most of these were due to nursing children in close proximity to the table, but a number resulted from the child upsetting a teapot or kettle on a stove, a hob, or a gas-ring on the floor. Saucepans (63) were often on the floor or, when on a fire or stove, the projecting handle was grasped by the child. A child, 2 years of age, fell and sat in a frying-pan placed on the floor. Some of the children who fell into washtubs or baths were just at the toddling stage and lacked proper supervision when in wash-houses and outhouses, and as a rule such injuries were extensive.

The burns fell into 3 groups. The most serious as regard extent and prognosis were those in which the child's clothes

were ignited; 6 out of 30 such patients died. This type was most common in girls, often being due to the hem of a nightgown or skirt becoming ignited as the child reached for the mantelpiece or stood too close to an unguarded fire. Some were the result of the child, or other children, playing with matches. Burns due to contact with fire-bars or hot grates were usually small in extent but deep in degree, and some occurred in spite of a fire-guard; one child, aged 16 months, climbed the fire-guard while unattended

TABLE I

Agents causing Burns and Scalds	Number of Patients	Died
Cup of tea (includes 3 coffee, 3 cocoa)	91	1
Teapot .. .. .	43	1
Kettle .. .. .	59	3
Saucepans and other cooking utensils	63	—
Plates of hot food .. .. .	9	1
Fall into pail of hot water, hot bath, wash-tub, boiler, etc.	20	2
Fireplaces, etc. .. .. .	25	—
Clothing set on fire .. .. .	30	6
Lighted paper, celluloid combs, etc.	9	1
Burst rubber hot-water bottle	5	—
Burst boiler .. .. .	2	—
Poultices .. .. .	3	1
Stood in quicklime .. .. .	1	—
Sunburn .. .. .	1	—
Car accident .. .. .	1	—
Baby born into pail of hot water .. .. .	1	1
Feet bathed with boiling water .. .. .	1	—
Placed on "chamber" containing boiling water	1	—
Cause unknown—"came home burned" ..	1	—
Burns .. .. .	68 (18.6%)	7 (10.3%)
Scalds .. .. .	298 (81.4%)	11 (3.7%)
Totals .. .. .	366	18 (4.9%)

and fell against the bars of the grate, and another, aged 2 years, was burned while playing with a gas-oven. In the third group, the burn, usually of small extent, was due to the ignition of celluloid combs or similar articles when the child, tiring of them as playthings, poked them into an easily accessible fire; these were serious in that the hands were often the parts most badly affected. The miscellaneous causes call for little comment; 3 out of 17 such patients died.

In the case of patients living within the boundaries of the city of Edinburgh an attempt was made to relate the circumstances of the accident to the home conditions and the geographical situation of the house. This has shown that the incidence is high in certain areas of the city where population is dense. The cases are concentrated in parts of the Old Town and in some parts of the newer municipal housing estates built on the outskirts of the city. This latter observation is important, as it appears to indicate that bad accommodation is not so prominent a factor as the domestic habits of the family. In some families more than one child had been scalded or burned on various occasions, and a few children had been injured more than once. The lives of the parents of these children are hard; families are often large, and it is all too common for the younger children, aged up to 5 years, to be left in the charge of other children only a few years older. This aspect of the problem has become increasingly important with the present difficulties in shopping, part- or whole-time work, etc.; and is not always relieved by such measures as have been introduced for the partial care of children, since many parents are unwilling to depute the care of their children.

#### Time Incidence

In 132 cases of the present series there was a record of the time of day at which the injury occurred (see Chart). The peak

Chart showing time incidence of injury (132 cases)

was reached in the early evening between 5 and 7.30 p.m., which is not unexpected. There were surprisingly few during the morning, but an unduly large number between 9 and 11 p.m. The occurrence of scalds in young children at midnight and 1 a.m. is noteworthy.

Burns and scalds are common during the winter months, but in examining a large series of over 800 cases it was found that admissions might reach an unusually high level in a particular month without relation to the season and for no evident cause. Table II is of interest in showing that the incidence in the last two months of 1939 and the first two months of 1940, when compared with that in the same four months in the previous five years, was found to be nearly twice as great. These numbers have since declined, but are still 40% above the pre-war level.

TABLE II.—Number of Children suffering from Burns and Scalds seen at Surgical Out-patient Department per Month (1934-42)

	1934-5	1935-6	1936-7	1937-8	1938-9	1939-40	1940-1	1941-2
Nov. ..	12	16	10	12	9	22	14	13
Dec. ..	11	15	12	12	20	24	14	22
Jan. ..	12	9	16	12	11	29	28	20
Feb. ..	16	5	16	15	11	22	15	15
Totals	51	45	54	51	51	97	71	70

This increase appears to be associated with the abnormal social conditions existing during these months of 1939-40: such as the closing of schools, cinemas, and other places of entertainment and the lack of recreational facilities, the "black-out," and a reduction in amount and quality of parental supervision of children, due to mental unrest, preoccupation of various kinds, and additional war work.

#### Age Incidence

In Table III the number of patients and deaths, and the mortality rate at certain ages, are shown. Most injuries occurred in the second year of life: 70% of the patients were less than 3 years and 88% less than 5 years of age. The mortality rate was high in the first, fourth, and fifth years; in the first year fatal injuries were often of small or moderate extent (5, 5, 5, 10, 20% of body surface), while in the fourth and fifth years they were usually extensive (10, 25, 45, 50, 50, 60, 65% of body surface). In the first year all were scalds; in the fourth and fifth years only two were scalds.

TABLE III

Age Group (Years)	Total Patients	Total Died	Burns		Scalds	
			Total	Died	Total	Died
0-1	45	5 (11.1%)	7	0	38	5
1-2	147	4 (2.7%)	24	1	123	3
2-3	65	1 (1.5%)	9	0	56	1
3-4	38	4 (10.5%)	8	3	30	1
4-5	26	3 (11.6%)	7	2	19	1
5-12	45	1 (2.2%)	13	1	32	0
0-12	366	18 (4.9%)	68	7	298	11

Further evidence on age incidence in children has been obtained from the Reports of the Registrar-General for Scotland, which show that in the years 1931-8, inclusive, 493 deaths, or 40.9% of deaths at all ages from burns, occurred in children of 5 years or under; of the 18 children of the present series who died 17 were aged 5 or less. The only significant difference in incidence between the two sexes was between the ages of 1 and 3 years, when males predominated (136 males, 76 females); the totals for all ages (up to 12 years) were 211 males, 155 females.

#### Extent of Injury

Thermal injuries may be classified according to their extent, site, and depth. In children the most important of these criteria is extent, since the ratio of surface area to body weight is highest at birth and decreases approximately as weight increases, and the systemic disturbances are usually related fairly closely to the extent of the injury. The danger of certain complications is greater in deep than in superficial burns and in burns affecting the flexures and the neighbourhood of orifices, and these factors were taken into consideration in deciding whether or not to admit patients. Comparison with previous series in regard to extent of injury is difficult, but it is the opinion of surgeons who have treated such patients for many years that more injuries of small extent are now treated in the in-patient department than was formerly the case.

From Table IV it will be seen that in 303 of 366 patients admitted the injury involved 15% or less of the body surface; most

patients—with lesions of less than 5%—were admitted because of the dangers of complications due to site or depth of the lesion, and none of this group of patients died. Of 244 patients with injuries of 5 to 15% of body surface, 6 died (1 of shock, 5 at later stages); of the remaining 63 patients 12 died (8 of shock, 4 at later stages). As the extent of injury increased so did the mortality rate, but the number of patients diminished. The importance of shock as a lethal factor is closely related to the extent of injury.

TABLE IV.—Extent of Injury in Relation to Mortality

Area (%)	Number of Patients	Deaths (No. Cases)	Shock	Mortality Rate (%)	
				All Cases	Shock
Less than 5	57	0	0	0.0	0.0
5-15	244	6	1	2.4	0.4
15-45	54	12	8	22.2	14.8
50-100	9	8	7	88.9	77.8

## First-aid Measures

Information was obtained in 265 cases regarding the first-aid treatment given by parents, relatives, neighbours, passers-by, or medical practitioners. In some cases more than one method had been used. One patient had been treated with four different medicaments—namely, cod-liver oil, flour, and baby powder to the raw surface, and castor oil internally. Another had been dressed with cotton oil, white of egg, and tannic acid jelly. The 116 substances used on 242 patients are listed below; no first-aid treatment was given to 23 patients.

Substances used at first aid on 242 Patients

Substance	Number of Patients
Olive oil	50
Various tannic acid jellies	5
Picric acid	45
Dry cloths, etc., etc.	7
Flour	10
Cotton oil	10
Onion juice	10
Castor oil by mouth	14
Flaxseed emulsion, etc.	8
Baking soda	6
Vaseline	6
White of egg	5
Butter	3
Syrup of figs by mouth	1
Cloth soaked in tea	1
Talcum powder	18
Starch	1
Cod-liver oil	1
Eucalyptus	1
Cold water	1
Soup	1
Glycerin	1
Milk	1
Vinegar	1
Calamine lotion	1
T.C.P.	1
Bone powder	1
Total applications	516
No first aid	23

The popularity of olive oil is an important factor, since, if a coagulant or other agent in a watery solution or base is subsequently to be used in the treatment of the raw surface, all the oil must be removed from the burn and adjacent skin, involving prolongation of local treatment and increased trauma to the raw surface. Oily and greasy substances do not appear to reduce the loss of plasma from the raw surface to an appreciable extent, and in some cases their application caused more pain than the initial injury. A variety of tannic acid jellies were used, but in no case was such treatment properly carried out. The commonest faults were the use of hopelessly inadequate amounts of jelly, resulting in the treatment of only part of the affected area, and the failure to cleanse the affected area before applying the jelly. For example, scalds due to the spilling of a cup of tea commonly extend on to the scalp and are always more extensive than they at first appear; before such injuries can be cleansed the hair must be shaved, and in the absence of this precaution infection is invariable. Picric acid is still frequently employed, in spite of the danger of liver damage which is known to be associated with its use. Twenty-three patients did not receive first-aid treatment; most of these were brought to hospital within a short time of injury, and no adverse effects were noticed in these cases. The use of baking soda is based on the common belief that it is soothing; flour and oils are thought to exclude the air. It is widely believed, among the older members of many of the families from which these children came, that a dose of castor oil helps to

"put away" shock following a variety of injuries, including burns and scalds. The dose varied, but as a rule the oil was vomited and purging seldom resulted; syrup of figs was also used for this purpose if castor oil was not available. Most of the remaining heterogeneous collection of substances represented all that was obtainable in the circumstances, applied without respect to action or value. Patients whose injuries had been covered only with a dry cloth or dressing were in a better state on admission than those with comparable injuries which had been treated with the wealth of the domestic pharmacopoeia.

## Discussion

Dr Quincey, writing in Edinburgh about a hundred years ago, stated that "three thousand children per annum—that is, three hundred thousand per century; that is (omitting Sundays), about ten every day, pass to heaven through flames in this very island of Great Britain." In a footnote he adds: "Their deaths are chiefly through the carelessness of parents." In spite of considerable advances there is still room for improvement. Donald (1930) reported a steady decrease in the number of children admitted and in the mortality rate at the London Hospital between 1899 and 1920. On the other hand, Wilson (1932) stated that in the Royal Hospital for Sick Children, Edinburgh, the incidence and mortality rate remained fairly steady during the period 1899-1920, but since 1920 the number of admissions had risen steadily, though the mortality rate had fallen. A possible explanation of this increase may be the rehousing of families from the Old Town in the new municipal housing estates at the periphery of the city, which began in 1922. This has resulted in a reduction in the number of patients treated at the dispensaries (Table V). It will be noticed that burns and scalds in children represent 5.6% of all new patients treated, and that this figure has remained remarkably constant in spite of the fall in attendance, indicating that the incidence of these injuries remains much the same in those areas of the city (chiefly the Old Town) served by this dispensary.

TABLE V.—Out-patient Attendances at a Dispensary

September to August	Total Out-patients	Burns and Scalds in Children
1936-7	2,034	112 (5.5%)
1937-8	2,104	106 (5.0%)
1938-9	1,487	90 (6.1%)
1939-40	1,299	69 (5.3%)
1941-2	1,705	102 (6.0%)
1942-3	944	60 (6.4%)
1943-4	793	37 (4.7%)
Total	10,219	576 (5.6%)

In the present series of children up to 12 years of age the burn-scald ratio is 1.4, as compared with Mitchiner's (1933) figures of 1.7 in 1933 and 3.2 in 1899. It is questionable whether the steady fall in the number of burns since 1899 which Donald reported has been contributed to by the Children's Act, 1908, to such a large degree as he believes. It seems equally probable that changes in environment in respect of fewer gas-lights, oil lamps, and open fires, greater provision for recreation and entertainment outside the home, and improvement in housing conditions have been the important factors. Of deaths at all ages from burns and scalds, 40% occur in children under 5 years of age. In this series 88% of 366 children under 12 years of age were less than 5 years old, and Donald's figures show that 86% of the 1899-1903 group and 88% of the 1924-8 group of children under 12 years of age were less than 6 years old. While the total number of burns and scalds at all ages may have declined, the proportion in children under 5 years of age remains the same. In the present series nearly all the injuries were due to domestic accidents arising out of a combination of the inquisitive and acquisitive instincts, lack of painful experience, carelessness and thoughtlessness of young children, together with inadequate supervision and failure to take preventive measures on the part of parents or responsible elders; actual neglect was extremely rare. These injuries were most common under cramped conditions in the poorer districts, but occurred also in small families living in uncrowded homes.

The limit of the degree to which the gross mortality rate in children can be markedly reduced by therapeutic measures is now being approached. From the evidence which has been cited

there is no doubt that nearly all these injuries can and should be prevented. To this end the following suggestions are made:

1. Intensive propaganda by posters exhibited in public conveyances, hospital and clinic waiting-rooms, schools, and cinemas. Such propaganda should give information as to the number of burns and scalds per year, with mortality rates; and a description, with diagrams, of the ways in which the accidents occur, how they may be prevented, what first-aid treatment should be applied, and where further treatment may be obtained.

2. Closer co-operation between hospital staffs and the social services. All such accidents involving children should be notified to a statutory or voluntary organization dealing with the welfare of children, or to the hospital almoners. The house concerned should be visited within 48 hours by a trained social service worker—preferably a woman—who would inquire into the circumstances of the accident, give advice regarding the prevention of a recurrence, and make a confidential report to the hospital or organization.

There are few, if any, circumstances more distressing than those attending the burning or scalding of an infant or young child. At once all is confusion and concern. While recognizing the difficulties and stress under which home treatment is carried out, the methods that had been employed in this series call for comment. The state of the injuries to which various types of coagulant jellies had been applied was creditable neither to the person who applied the treatment nor to the jelly concerned. When used properly on a suitable case such jellies may be valuable and efficient agents, but their employment by those not conversant with the indications for their use and with their inherent dangers is to be discouraged. A recommendation that the patient be removed to hospital without any form of local first-aid application may be thought callous, but it cannot be too strongly stressed that first-aid treatment of the kinds commonly found in this series is unnecessary, meddlesome, and almost invariably harmful. The guiding principles are two: the treatment of shock already present, and the prevention, so far as is possible, of further shock; the latter implies protection of the raw surface, but not its over-medication. Both principles can be followed by interfering as little as possible with the patient and the lesion. The details of first-aid treatment have been fully stated in E.M.S. Memorandum No. 7, Department of Health for Scotland, 1941.

#### Summary

A review has been made of 366 children up to 12 years of age, suffering from burns and scalds, who were admitted to the Royal Hospital for Sick Children, Edinburgh, from June 1, 1938, to July 31, 1942, with special regard to the social aspect of the injuries.

The circumstances of the accident, including the time of day, causal agent, age of patient, and the extent of the injury, have been analysed. The results of these analyses, combined with the geographical and social distribution within the area served by the hospital, show that the problem of burns and scalds is primarily a social one, which, it is believed, can best be solved by suitable educative propaganda directed to that part of the community most affected.

The first-aid treatment given to these patients was also examined; in the great majority of cases it had been badly done or was of an undesirable nature.

The mortality rate in this series of 366 burns and scalds was 4.9%.

Standard rates of pay for all nurses in mental hospitals and institutions in Scotland are recommended by the Scottish subcommittee on nurses' salaries, and the general effect is to increase salaries by 4s. or 5s. a week, thus bringing pay and also conditions of service generally into line with those in England. The starting salary of male nurses will be £2 18s. a week, rising to £4 11s. 6d. as charge nurses; the rates for women are 11s. less. There is to be an additional 4s. a week for nurses on night duty, and a standard working week of 48 hours is suggested, except in the Royal Asylums, where, in accordance with practice, the standard week varies between 48 and 54 hours. Nurses in mental institutions will receive a cash payment of £2 10s. on passing the preliminary examination and £5 on passing the final. Annual leave is to be 21 days. It is hoped that the new scales will result in increased recruitment of nurses for mental hospitals, where training is given not only for the State Register examination but also for the certificate of the Royal Medical-Psychological Association.

## HEAT IN THE TREATMENT OF SHOCK.

BY

ANDREW W. KAY, M.B.Glas., F.R.C.S.Ed.

Hall Tutorial Fellow, University of Glasgow

The application of heat has become fully established as a cardinal principle in the treatment of traumatic shock. It has been believed to exert a favourable influence, mainly by relieving the cutaneous vasoconstriction and thus augmenting the venous return. The possibility that the cutaneous vasoconstriction is a compensatory mechanism and that heat may be harmful has only recently been entertained.

To assess the value of heat in clinical cases of traumatic shock is difficult, for the level of shock is influenced by many variables which cannot be controlled. It seemed useful therefore, to investigate the effects of heat, as usually applied in the treatment of shock, upon normal subjects. This report relates to such an investigation carried out upon healthy adults exposed to heat under a "heat cradle." While the results cannot properly be regarded as applicable to shock, they do at least suggest that the value of heat in shock deserves further critical assessment.

#### Experimental Method

Subjects used in this investigation were young adult male who were either convalescent from minor surgical procedure or were awaiting such operations as herniorrhaphy or excision of haemorrhoids. Observations made were: (1) arterial blood pressure; (2) venous blood pressure; (3) pulse rate; (4) oral temperature; and (5) the patient's clinical condition.

The venous-pressure apparatus employed consisted of a No. 19 intravenous needle fitted to a three-way stopcock. This stopcock is connected at one inlet to a reservoir of normal saline and at its other inlet to a manometer of 4 mm. calibre. Venous blood pressure is therefore recorded in millimetre of saline solution. Zero was arbitrarily set at the level of the manubrium sterni. When the apparatus is in use repeated observations can be made, and between these readings a continual drip of saline prevents clotting within the needle. By this method the normal range was found to be 60 mm. to 80 mm. of saline solution and the average resting venous pressure in 40 young adults was 69.5 mm. At least five minutes must elapse after venepuncture before readings can be accepted as being reliable.

Heat was applied by means of the hot-air cradle for one hour, the temperature varying between 38° and 40° C. Observations were made before the application of heat, at ten-minute intervals during its application, and for 40 minutes thereafter. To bring the experiment into line with the treatment of shock, normal saline was administered intravenously to 10 subjects in amounts ranging between 200 and 1,200 c.cm. In 5 other cases plasma was administered intravenously in amounts ranging from 250 to 700 c.cm.

#### Experimental Findings

The record of Case 5 is given in detail (see Table), with a graphical record (Chart I). The combined records of all cases are shown in Charts II and III. Mean curves are used in place of tables, and it is to be noted that the curves of individual cases approximate closely to the mean.

Certain constant changes were observed: (1) a progressive fall in arterial blood pressure; (2) a rise in venous blood pressure; (3) a rising pulse rate; and (4) a rise in oral temperature. In addition to these findings, however, the most striking observation was the effect of the hour's exposure to heat on the patient's general condition. Three experiments had to be abandoned owing to the severity of symptoms and the resulting anxiety expressed by the patient. In these cases headache, nausea, and exhaustion were prominent symptoms. Flushing was evident before the termination of the period of exposure to heat in every case. Frontal headache was common, and frequently lasted from 12 to 24 hours after the end of the experiment. In 9 cases symptoms of dehydration were present in varying degree—viz., dry tongue, weakness and thirst. In all cases general perspiration was noted. In 6 cases nausea was present, and vomiting occurred in two of these. Other symptoms were abdominal discomfort, muscular

pains and exhaustion. These subjective effects were not prevented or lessened by concomitant intravenous administration of saline or plasma.

### Discussion

It is not the purpose of this paper to give a detailed explanation of the circulatory changes observed. It is suggested, however, that the essential factor is a general peripheral dilatation. This is borne out by the flushing of the face and trunk which was observed in every case. This peripheral dilatation results in a diminution of the pressure gradient between the arterial and venous sides of the circulation. A lowering of the arterial blood pressure and a rise in venous

TABLE I.—Detailed Record of Case 5.

Time Mins.	Pulse Rate	V.B.P. (mm. Hg.)	A.B.P. (mm. Hg.)	Oral Temp. (°C.)	Clinical Notes
0	50	73	130.75	38.2

110	56	85	122.70	38.8	No change in symptoms; headache for 12 hours. Feeling of exhaustion persisted for 5 hours

CHART I.—Record of Case 5.

blood pressure are so produced. The increase in pulse rate occurred in all subjects quite independently of their excitability. It may be a direct result of increased pressure on the right side of the heart reflexly producing a rise in heart rate (Bainbridge, 1915).

It is considered that the result of this study shakes the confidence which has for so long been placed in heat therapy for patients suffering from traumatic shock. In the normal subjects, investigated definite evidence of dehydration occurred after exposure despite the concurrent administration of intravenous fluid. This is not consistent with the aims of treatment for patients already suffering from the effects of fluid loss.

No one has defined adequately the term "shock," although many have their own conception of this complex clinical entity. Most, however, will concede that a lowered arterial blood pressure is present in all but a small minority of cases. These experiments have revealed a constant and progressive lowering of blood pressure when normal subjects were exposed to the hot-air cradle. Most accepted forms of treatment aim at raising blood pressure, and so, for this further reason, prolonged heat must be regarded as harmful.

It is also recognized that in shock there exists arteriolar constriction (Meek and Eyster, 1921). This is primarily a compensatory mechanism. The flushing which was observed so constantly after application of heat indicates peripheral dilata-

tion. In addition to overthrowing the compensatory mechanism this leads to increased fluid loss by capillary filtration, and thus adds to the state of dehydration which already exists and which has been augmented by perspiration.

CHART II.—Mean curve of 10 cases receiving saline intravenously.

CHART III.—Mean curve of 5 cases receiving plasma intravenously.

### Summary

Fifteen normal subjects were exposed for one hour to the hot-air cradle. Intravenous saline was administered to 10 of these, and intravenous plasma to 5.

A progressive rise in pulse rate and venous pressure, together with a progressive fall in arterial blood pressure, was observed in all cases. Symptoms resulted, including nausea, vomiting, dehydration, headache, perspiration, muscular pains, and exhaustion. In certain cases these were severe.

These findings would appear to contraindicate the prolonged use of heat in the treatment of patients suffering from traumatic shock.

I wish to express my grateful thanks to Prof. C. F. W. Illingworth and Prof. Noah Morris for their encouragement and helpful criticism. This work was done while in receipt of a grant from the Medical Research Council.

INFLUENZA "A": AN ACCOUNT OF A MINOR  
EPIDEMIC

BY

T. H. DONNELLY, M.B., B.S.  
Flight Lieut., R.A.A.F.H. P. HUGHES, M.B., Ch.B.  
Flying Officer, R.A.F.V.R.D. ROBERTSON, M.B., B.Ch.  
Flying Officer, R.A.F.V.R.

AND

ELLIOT PHILIPP, M.A., M.R.C.S.  
Squadron Leader, R.A.F.V.R.

On March 30, 1943, a Canadian airman went sick with symptoms corresponding to those known to the lay public as "influenza." He was tired and had slight cough and headache; eye movements were painful and he felt hot and then shivery. On examination his temperature was 102° F., pulse 84, and respirations 18. There was slight pharyngeal inflammation, but no glandular enlargement or nasal catarrh; lungs, heart, and all other systems were normal. He was put to bed. His temperature remained above 101° F. for 36 hours, and then dropped to normal. The patient was fit for discharge within four days of admission.

On April 3 an English officer reported sick with similar symptoms and signs. No special investigations were made, and after four days in bed he was perfectly fit again.

On April 14 an airman reported sick. Symptoms were similar to the previous two cases except for slight harshness in breath sounds at the base on the right side. Temperature was normal after 60 hours in bed. On the third day of illness slight pain was felt in the right side of his chest; breath sounds were diminished, but temperature became quite normal. After two days, as the patient did not seem to be making quick recovery in spite of the normal temperature, he was sent to hospital for x-ray, which showed tuberculous infiltration in the right apex, and this result was confirmed by tuberculosis-positive sputum.

On April 16 a W.A.A.F. reported with a temperature of 101° F. She had headache, a slight cough, and a sore throat. Put to bed, she recovered in three days. On the next day an airman reported with similar signs and symptoms, which also cleared in three days; but from that date cases occurred in increasing numbers, as shown on the graph of incidence of the epidemic (Fig. 1). Ten cases were reported on April 21;

FIG. 1.—Curve of incidence of the epidemic.

it then appeared obvious to us that an epidemic of a virus infection was occurring, and it seemed likely that the infection might be one of true influenza. Investigations were carried out, and on April 23 some of the 30 patients then in bed were picked out at random for (1) chest radiography; (2) differential blood count; (3) throat swab; (4) blood culture; (5) sputum examination; (6) titrations of antibodies in blood against influenza viruses A and B.

By this date the patients being admitted had much severer symptoms and very definite signs. They felt too ill to report sick, and several were found lying on their beds in their quarters feeling very poorly. In most cases headache was

severe; there were slight soreness of the throat, nasal catarrh, and some nausea. There was much sweating with shivering between times, and also a variety of severe signs and symptoms which we discuss below.

On examination temperatures were found to be between 102° and 103° F.; the eyes were very red and the faces flushed, suggestive of early morbilli, with, in some cases, enlargement of cervical and submaxillary glands. Tongues were furred, pharynges injected (but with no membrane) and in some cases of a violaceous tinge. In the chest, post-tussive "sticky" crepitations were heard in all arcs. Breath sounds were harsh and vesicular in type, with prolonged expiration. Low backache was a feature of most cases. The urine was normal except for traces of albumin in one or two cases. Of the 12 chests x-rayed, seven had no abnormality. Only one showed marked congestion with some consolidation at the right base.

The differential white blood cell count in a typical case was: total white cells, 5,300 (polymorphs 71.5%, lymphocytes 23%, monocytes 5%, eosinophils nil, basophils 0.5%). The highest total white cell count was 7,600 (polymorphs 54.5%, lymphocytes 31.5%, monocytes 12%, eosinophils 1%, basophils 1%). Throat swabs in most cases showed moderate growths of pneumococci, *Strep. viridans*, *N. catarrhalis*, or *Strep. haemolyticus*. Blood cultures revealed nothing. Sputum examinations disclosed little of interest, except in the case with tuberculosis.

Titrations of antibodies against influenza viruses A and B by the Hirst method (inhibition of the agglutination of fowl red cells by influenza virus) gave these results:

Case	Sample	Virus	
		A	B
1	I	1/32	1/32*
	II	1/192	1/64
2	I	1/48	1/16*
	II	1/384	1/32
3	I	1/256	1/96
	II	1/256	1/96
4	I	1/96	1/64
	II	1/128	1/32
5	I	1/128	1/32*
	II	1/1024	1/32
6	I	1/64	1/16*
	II	1/1024	1/16

\* In each case blood sample I was taken within two or three days of the onset of the disease, and blood sample II about 14 to 20 days later.

Dr. C. H. Andrewes, F.R.S., of the Medical Research Council, under whom Miss K. C. Mills so kindly did the tests, reported: "No case showed a significant change in antibody level against B, whereas four showed a good rise against A. (These have been marked with an asterisk.) As to the diagnosis of Cases 3 and 4, it has been noticed in numerous outbreaks, both in the United States and over here, that cases giving no evidence of infection with influenza A virus turn up in the same outbreak as virus A infection. It has been suggested that when influenza hits, as it sometimes does, a patient who already has good A antibodies the infection may cause no further rise. This may have been the case with Case 3." Dr. Andrewes (1942) has discussed the question in an address.

On April 24 only one case was admitted, but April 27 brought the "crest" of the second wave of the epidemic. Cases admitted after that date became progressively less severe, and only one or two were admitted after May 12.

## Discussion

Although only 68 cases actually reported sick it is known that there were many airmen who felt "a bit off colour" during the period of the epidemic and who probably suffered from a "subclinical" attack of influenza A. Of our severe cases, one patient showed chest complications at a very early stage, although by portable x-ray findings no pneumonia was actually present. Clinically his case seemed to be quite a definite pneumonia, and was treated as such. Another patient showed as his first severe sign marked and persistent irregularity of the heart rhythm. He was treated with "absolute rest" for three days, at the end of which time normal rhythm without adventitious signs had been re-established. Severe low backache was experienced by two or three patients, and had there not been an epidemic of influenza this might easily have

been mistaken for a renal condition. We would like to point out that had we seen the case with the bad chest or the case with irregularity of the heart or those with the very severe backache at any other time than during an obvious epidemic we would have sent them into hospital under varying diagnoses, and thus almost certainly have spread the epidemic.

We consider that the period of incubation is between 24 and 48 hours, but it may be as high as 96 hours.

### Treatment

All patients were placed on a fluid diet on the first day of the disease and all received diaphoretic mixtures. The diet was increased each day, and the diaphoretics were continued until the patients were fit to leave bed. Cough, where troublesome, was treated with a codeine linctus.

Sulphapyridine treatment was resorted to for all patients whose temperature had risen above 103° F. The dosage was 2 g. as an initial dose and 1 g. four-hourly. No patient had more than 8 g., and the temperature was normal in each case before that dosage had been taken. It did appear as though the sulphapyridine had definitely assisted the drop in temperature. The literature gives conflicting reports on the efficiency of sulphapyridine in influenza A, but it seems logical that in a disease in which the temperature is high owing to virus infection and in which most throat swabs demonstrate the presence of pneumococci or streptococci the use of sulphapyridine or some other drug of the group in severe cases is indicated.

The weakness that so many writers describe after influenza was not apparent in this series of cases, and all patients were fully fit seven days after leaving bed. These seven days were spent doing light duties only. There were no serious complications, except in the case proved to have tuberculosis. It may well be that had this patient not developed influenza his tuberculosis would not have been brought to light at the early stage at which it became apparent.

As stated by many writers, the epidemic occurred in two waves; and we noticed also that the curve of incidence of the cases was not dissimilar in shape to an average temperature curve of the severer cases (Fig. 2). It was observed, too, that

FIG. 2.—Average temperature curve.

the epidemic began in warm dry weather with a mild breeze which persisted from April 14 to April 21. The weather then deteriorated, and there was some rain; but on the 24th it improved, and became quite warm by the 26th. It may be that, somehow, the weather had no effect on the incidence of the disease, as rain fell again on April 28 or 29.

The ultimate object, of course, of the study of any outbreak is to indicate some way of preventing another occurring and, in the case of influenza, especially of preventing such a catastrophe as the 1918-19 epidemic. We can only state that, in our opinion, isolation is of the very greatest importance. Every case of even mild cold that occurs during a known epidemic should be rigidly isolated. By far the greatest proportion of our cases occurred on a satellite aerodrome, and all cases from that aerodrome were taken to the main aerodrome to be nursed in houses separated from all the other buildings on the camp. The only patients reported from the main camp after April 18 were medical personnel and ambulance drivers. Approximately half the medical personnel looking after the cases developed influenza. These medical personnel did not leave sick quarters or associate in any way with other members of the camp. It is probably for this reason that no cases occurred among the thousands of airmen on the main camp.

So far as other preventive methods go, it would certainly be worth while trying experimentally to vaccinate large bodies of men against influenza A a few months before the reckoned time (if it is possible to reckon!) when another epidemic should occur. The work of Horsfall (1939, 1941) in this connexion is especially interesting.

Sterilization of the air by ultra-violet light and propylene-glycol spray has been attempted elsewhere, but in view of our findings that wet weather coincided with the decrease in the waves of the epidemic it may be that simple moistening of the air would have some beneficial effect.

### Summary

An account is given of a small epidemic of influenza A.

Indications as to the treatment of such an epidemic when occurring on a military camp are given.

The importance of bearing in mind the possibility of influenza when certain symptoms not normally "textbook" arise, as well as the necessity for excluding tuberculosis, is stressed.

Our thanks are due to Dr. C. H. Andrewes and Dr. A. Morton Gill for the very kind advice and help given, as well as to Wing Commander Hudson, Wing Commander Church, Squadron Leader Wynroe, Squadron Leader Campbell, and our own sick-quarters staff for their great assistance.

## ESTIMATION OF HAEMOGLOBIN BY PHOTO-ELECTRIC ABSORPTIOMETERS

BY

J. M. PETERSON, D.Sc.

Lecturer in Experimental Physiology, the Physiology Institute, Cardiff

AND

D. H. STRANGEWAYS, M.A., Ph.D.

Assistant Lecturer in Histology and Embryology, University College, Cardiff

Changes in intensity of light and in the electric properties of the photo-cell have been advanced as sources of error in the estimation of haemoglobin by means of photo-electric absorptiometers (M.R.C. Report, 1943). This objection to a method which at the moment appears to offer the best means of accurate estimation of haemoglobin may be justified when it refers to absorptiometers which employ a single photo-cell and which indicate the light-absorbing power of the solution by the extent of deflection of a galvanometer. When, however, a null technique is employed with an apparatus incorporating two opposed photo-cells, error due to these changes has been found, in practice, to be eliminated. The procedure by which such error is avoidable can be simply stated without detailed description of method.

### Outline of Procedure

The concentration of haemoglobin is measured in terms of the width to which a slit has to be adjusted to pass through the haemoglobin solution that quantity of light which gives a definite output of current from the photo-cell on which the transmitted light is focused. With the light to one photo-cell passing both through the filter whose light absorption in terms of haemoglobin is known and through the adjustable slit set at the haemoglobin value of the filter, the light to the other cell is varied to give a null reading on the galvanometer. The standard filter is then replaced by the blood solution to be measured and the light adjusted by means of the slit till the null reading is again obtained. On replacing the standard filter and resetting the slit to the filter value the instrument should give the null reading. If there has

been a significant change in either or both of the photo-cells or in the light source the null reading will not be obtained, and the light to the balancing photo-cell will have to be readjusted to give a null reading before repeating the estimation. The estimation is reliable only when the null reading is obtained with the standard filter both before and after making the estimation with the blood solution.

As the standard filter and the blood solution do not necessarily transmit the same wave-lengths, it is essential, for this procedure to give accurate results, either that any change in current output from the photo-cell must be the same for all effective wave-lengths or the range of wave-length employed must be so narrow that such a wave-length difference, if it occurs, is without effect.

Our justification for claiming that changes in light intensity and in the condition of the photo-cells need not cause error is this: With an absorptiometer of the opposed-cell type using barrier-layer selenium photo-cells and NaOH-blood solutions, the reading on the instrument for a given solution is unaltered with wide differences of light intensity; further, the haemoglobin value of a solution determined immediately the photo-cells are illuminated is unchanged when redetermined after the apparatus has been in use for some hours, when the condition of the cells has markedly altered (as shown by the galvanometer deflection produced by standard illumination).

#### Some Observations

In estimating haemoglobin by photo-electric means we have made a few other observations that may be of interest. Certain advantages of the alkaline haematin method have already been advanced by Clegg and King (1942). In some ways the procedure employed in the present work differs from that of other workers. It has been found that accurate measurements can be made with NaOH-blood solutions without the necessity for either heating the alkaline solutions or forming alkaline haematin indirectly by conversion from acid haematin. 0.02 or 0.04 ml. of human blood added to 5 ml. of decinormal NaOH, estimated within five minutes, gives a value greater than 95% of the maximum. For very accurate work it is an advantage to let the solution stand overnight and to use only the supernatant liquid. There is always a slight deposit, but the supernatant liquid gives a constant maximum absorption for about five days. This rapid rate of denaturation is not necessarily true of all bloods. That of the ox, for example, requires some hours for a satisfactory equilibrium to be established.

A further advantage in the use of a strong alkali lies in the fact that while slight clotting in the pipette, which may be undetected by macroscopic examination, causes a considerable error in the absorptiometric estimation of an aqueous oxyhaemoglobin solution, the clot is readily broken down in decinormal NaOH and the supernatant fluid gives a true reading.

The region of the spectrum best suited for accurate photo-electric estimation of alkaline haematin has been investigated, employing a wide range of colour filters. A spectroscopic examination of two alkaline blood solutions, representing extremes of concentration of haemoglobin, show marked differences in light absorption in three regions of the visible spectrum—viz., (1) in the band about 600  $m\mu$ , (2) in the long-wave end about 750  $m\mu$ , and (3) in the short-wave end to about 495  $m\mu$  for the weaker solution and to about 525  $m\mu$  for the stronger. Decidedly the best results, as measured by change in photo-cell current with change in haemoglobin concentration, have been obtained in this last region using a Wratten 45A filter, which gives light transmission from 430  $m\mu$  to 540  $m\mu$ , with maximum at 470  $m\mu$  and a smaller transmission in the ultra-violet. This absorption region is not so specific for alkaline haematin as is the 600  $m\mu$  band, but the degree of change of absorption with change in concentration of alkaline haematin, as indicated by the photo-cell, is so much greater here than in the 600  $m\mu$  band, as delimited by available colour filters, that its use is justified. In estimating total blood pigment, the lack of specificity of the shorter-wave region could be significant only if one were dealing with abnormal blood containing an appreciable quantity of some pigment not convertible to alkaline haematin by decinormal NaOH. Further, in the wave-length range transmitted by the Wratten 45A colour filter the absorption by blood plasma is insignificant, as shown by the extent to which the absorption by decinormal NaOH is increased by the addition of plasma to it. In a series of experi-

ments the addition of 0.02 ml. of plasma to 5 ml. of decinormal NaOH did not, in any instance, increase the absorption by more than the equivalent of 0.1 g. Hb per 100 ml. of blood, and in some instances there was no increase. It is obvious that the plasma plays no significant part in the estimation.

The accuracy obtained in photo-electric estimation of alkaline solutions of blood is highly satisfactory. Replicates of 0.02 ml. from the same sample of blood with an oxygen capacity of about 20 ml. per 100 ml. of blood can be estimated with a standard deviation of 0.1 and with a standard error of 0.04 for twelve estimations. When 0.04 ml. of blood is used the error is less.

In the absence of an absolute standard of reference we have expressed our measurements in terms of oxygen capacity, and have found that the curve relating absorptiometer reading to relative concentrations of haemoglobin, as determined by exact dilution, coincides satisfactorily with that relating absorptiometer reading to oxygen capacities of the same relative magnitudes and determined by the van Slyke manometric method.

From the observations made it seems justifiable to claim that the reliability of the absorptiometric method of measurement here described is such that, provided the blood does not contain appreciable quantities of haemoglobin derivatives inconvertible to alkaline haematin by decinormal NaOH, the only significant errors involved in estimating the total pigment lie in the sampling (Peterson, Strangeways, and Jordan, 1943) and in the lack of an absolute standard.

#### Summary

An answer is given to the criticism that changes in light intensity and in the electric properties of the photo-cell result in unavoidable errors in the absorptiometric estimation of haemoglobin. Certain facts relating to the accuracy of the estimation are discussed.

## Medical Memoranda

### Staphylococcal Pyopneumothorax in an Infant: Recovery

The following case record may be thought interesting enough to merit publication.

#### CASE HISTORY

A female infant was born of a healthy mother on Dec. 14, 1942 at the West Middlesex County Hospital. The infant weighed 7 lb. 5 oz. at birth and progressed satisfactorily until Dec. 20 or breast-feeds complemented with national dried milk. On that date she developed diarrhoea, with orange stools, and vomited once. She was transferred to the children's isolation ward, where she was found to be slightly dehydrated. She seemed to make a little progress on graduated feeds (glucose-saline, dilute lactic acid milk, and expressed breast milk) until Dec. 31, when she suddenly became much worse, with watery orange stools and severe dehydration. An intra venous drip was necessary to correct the latter, and, owing to the poor oral intake of fluids, was continued until Jan. 6, 1943. By that time she had developed thrombophlebitis of the internal saphenous vein, into which the drip was running. She had a slight temperature for two days, but this subsided when the drip was stopped. She also had two septic fingers and a septic toe. She improved sufficiently to go to the breast, for the mother's milk was coming better by then. On Jan. 13 she suddenly collapsed at the breast and was found to be pale, cyanosed, and almost pulseless. Later when examination was possible, her temperature was 103° F., pulse 140, and respirations 48. The percussion note was impaired at the left base, where bronchial breathing and pleural rub were found on auscultation. A diagnosis of pneumonia was made, and the child was put in an oxygen tent and given a course of sulphadiazine (8 g in six days).

During the next week the temperature subsided but did not reach normal, and the respiration rate increased. On Jan. 21 slight oedema of the legs was noticed. By the next morning the oedema was so gross that the legs looked like sausages, and the body wall was also dropsical. On examination of the chest the respiratory excursion were found to be minimal, respiration rate 60, heart sounds muffled at the left base and accompanied by harsh crepitations. The apex beat could not be located. A radiograph (portable) revealed gross displacement of the mediastinum, which was bowed out almost into the right axilla. It was thought that this bowing might have kinked the inferior vena cava, thus causing the oedema of the legs.

The child's appearance at this time was ghastly, with half-closed upturned eyes, greyish pallor, scarcely perceptible thoracic movement, a grossly distended abdomen, and swollen legs. The chest was needled at 9 p.m. on Jan. 22 and air rushed out under pressure. About 50 c.cm. was withdrawn. The oedematous legs were scarified and wrapped in sterile dressings. Next morning there was no oedema, nor did it subsequently reappear. Re-exploration of the chest resulted in a small quantity of pus but no air. On Jan. 24 another 50 c.cm. of air and a little pus were aspirated. On the 25th about 20 c.cm. of thick greenish-yellow pus was withdrawn. From the pus on each occasion *Staph. aureus* was cultured.

In view of the large quantity of pus obtained, closed intercostal drainage was decided upon, and at 12.30 p.m. on Jan. 25 a rubber catheter was inserted by means of a trocar without anaesthesia. A considerable quantity of pus gushed out under pressure. The apparent relief was immediate, the respiration rate falling from 100 to 45 in a few minutes. Continuous underwater drainage was maintained for three days, when the pus became too thick to pass through the catheter, so a wider tube was inserted. A radiograph taken on Jan. 25 showed the return of the heart to a more normal position. By the 31st there was very little discharge, and closed drainage was replaced by a short tube draining into the dressings. Between Jan. 26 and Feb. 2, 8 g. of sulphathiazole were given and a suspension of sulphapyridine powder was instilled into the pleural cavity twice a day.

The infant was not yet out of the wood. Her respiration rate had again risen to 70-80; this was partly attributable to the gross abdominal distension, which resisted all forms of treatment, such as charcoal by mouth, pitresin by injection, and the passage of a latex-tube. The diarrhoea had by this time quite subsided, and she was taking bottle feeds of breast milk well. On Feb. 5 the temperature once more shot up to 103°. The signs suggested a left-upper-lobe pneumonia. There was scarcely any discharge from the sinus, and needling failed to reveal pus elsewhere. She was given yet another course of sulphadiazine (8 g.) and local irrigations with 1:2000 propamide b.d., but she continued to run an intermittent though subsiding temperature until Feb. 27. On Feb. 13 she was put to the breast, and later resolutely refused bottle feeds; within 24 hours she was for the first time entirely breast-fed. From that time she never looked back, and was discharged on March 8, weighing 7 lb. 12 oz. and gaining steadily. The sinus was by then completely healed.

In addition to the above therapeutic measures she received three transfusions of fresh citrated blood (450 c.cm. in all) on Jan. 25, Feb. 2, and Feb. 19. She also had a course of vitamin B injections (1 mg. daily for three weeks).

Two radiographs were taken after discharge. The first, on March 12, showed that the left costophrenic angle was almost clear, but there were signs of bilateral bronchopneumonia. She was last seen on April 2, when she was a bonny child weighing 9 lb. 9½ oz. (a gain of nearly 2 lb. in 3½ weeks), entirely breast-fed, and showing no signs of her stormy passage except the four transfusion scars, a minute scar at the site of the intercostal drain, and a scarcely perceptible radiographic shadow at the left costophrenic angle.

#### COMMENT

The pyopneumothorax in this case may be assumed to have been due to the rupture into the pleural cavity of a lung abscess, itself caused by a septic embolus. Staphylococcal lung abscesses have been reported following skin sepsis (the infant had septic fingers from the start), but a more likely source in this case was the thrombophlebitis caused by the perhaps unduly prolonged intravenous drip. The rupture of the abscess into the pleura may be assumed to have occurred on Jan. 21, when oedema of the legs appeared and the signs of respiratory distress became acute.

Features of interest in this case are: (1) the remarkable degree of mediastinal displacement, the presumed cause of the oedema of the legs; (2) the child's recovery from such a severe illness starting at the age of 1 month, when she was not yet through an attack of neonatal diarrhoea—itsself having a mortality rate of 80%; (3) the successful establishment of breast-feeding after the mother had been expressing her milk for a month the child was in the oxygen tent.

I wish to thank Dr. Cook, medical superintendent of West Middlesex County Hospital, for permission to publish this case, and Messrs. May and Baker for the supply of propamide used in irrigations. I would also like to express my appreciation to the nursing staff concerned, and especially to Sister Jones and Staff Nurse Moloney, on whom the bulk of the nursing of this exacting case depended.

PATRIA GAIRDNER, M.D., M.R.C.P.,

Assistant M.O.H., Oxfordshire County Council.

T. C. Jaleski and E. T. Morrison (*Amer. J. med. Sci.*, 1943, 206, 449), who report two cases in healthy adults, state that congenital heart block is rare, only 80 cases having been described up to 1942. The first case, which had been studied for five years, was a healthy woman, aged 20, with no cardiac symptoms and no other apparent anomalies. The second case was a woman, aged 31, who had been followed from birth and had had no cardiac symptoms except for some syncopal attacks. She had had two normal pregnancies without any serious cardiac disturbance.

## Reviews

### ALMROTH WRIGHT'S COLLECTED PAPERS

*Studies on Immunization. First Series. Researches from the Inoculation Department, St. Mary's Hospital—III.* By Sir Almroth Wright, M.D., F.R.S. (Pp. 421, 25s.) London: William Heinemann, 1943.

Some time ago (Aug. 8, 1942) we reviewed a volume containing papers written by Sir Almroth Wright during and shortly after the last war on *The Pathology and Treatment of War Wounds*. This was the first of a projected series of five republications in book form of the work of Wright and his collaborators.

Volume III is entitled, *Studies on Immunization. First Series*, and though a reprint with few changes of a book published in 1909 it actually consists of papers originally published between 1897 and 1908. There are very few living medical authors who could republish so imposing a body of work mainly carried out more than forty years ago, and fewer still, if any, who would venture to do so if they could. The earliest papers are among the most interesting, and almost unconnected with the main subject of the book; that by C. Birt and G. Lamb on the agglutinin content of the blood in what we now call undulant fever, and its variations in the course of the disease, contains much useful information. The rest, which treats of the therapeutic use of vaccines, can be looked upon in one or other of three ways.

It is certainly a convenient reassembly of historic papers, which will save the inquirer trouble in obtaining the originals; during the present scarcity of paper for more urgent scientific purposes this in itself does not seem a sufficient reason for printing such a book. The author's own view, expressed in a foreword written for this publication, is that practitioners not conversant with some of its principles are "not properly qualified to take charge of patients suffering from bacterial infections." In fact he seems to stand by his earlier pronouncements, and would presumably still advocate the treatment of tuberculosis by injections of tuberculin controlled by opsonic index estimations, as well as other forms of vaccine treatment the efficacy of which is not generally admitted. We venture to predict that few readers will accept this judgment. It would be surprising if ideas developed so early in the evolution of a young science remained fully acceptable at the present day, and, as is to be expected, adverse criticism of these papers in the light of more modern knowledge is inevitable. To cite only one example, that which represents serum treatment's vaccine treatment in disguise—it being suggested that bacterial products with which the animal has been immunized are present in the serum and are the source of its activity—cannot be taken seriously. A third way of regarding this publication is as a stimulus to more critical thought and to further investigation. We may disagree with most of it, but it would be more constructive and useful if we had something practical to offer in its stead. We can now successfully treat many acute infections, but we are very much as we were in dealing with many chronic ones. We do not know why they recur or persist in an otherwise healthy individual, in spite sometimes of a high degree of humoral immunity, or at least of every effort to produce it. The only adequate answer to the vaccine doctrine will be to expose the undiscovered factor of which it takes no account.

### ASSESSING THE FOSTER PARENT

*In Quest of Foster Parents.* By Dorothy Hutchinson. (Pp. 145, 11s. 6d.) New York: Columbia University Press; London: Oxford University Press, 1943.

Even before the war many children every year had homes found for them with adoptive parents or guardians by voluntary agencies or local authorities. The need for evacuation from the towns turned into home-finders many thousands of persons with neither experience nor knowledge. This book should have been available at that time, but its value will none the less be permanent and considerable. It fills a want which many workers in this country must have felt. Miss Hutchinson, who is assistant professor of social work in the New York School of Social Work, restricts herself to the choice and evaluation of foster parents who apply to social agencies or to social

workers for children, and to the psychology of home-finding it may affect both the worker and the foster parents. As she admits, home-finding is only one part of child placement, and knowledge concerning it should be fitted into place in the larger pattern. She rightly regards the reason of a would-be foster parent for wanting a child as a vital indication of what kind of a person he is and what kind of a foster parent he will be; her first chapter therefore deals with the wishes of parenthood and some of the chief emotional patterns that are favourable or unfavourable. She then passes to the situation of the home-finder interviewing a prospective foster mother, and the converse one in which the home-finder visits the prospective home. She gives useful warnings on the assessment of references, and much help in the difficult and sometimes painful task of refusing a foster parent. In the United States home-finding in wartime has been expanded by the needs of families whose fathers have left for military service and whose mothers have to go to work and can no longer give sufficient time to the home. It has not yet assumed the tenacity of our evacuation problems. Nevertheless much of what Miss Hutchinson says under this head is fully relevant to us, especially her emphasis on the need for trained social workers to back up the foster parents. She calls her book in a subtitle "A Point of View on Homefinding," and it is a very wholesome and down-to-earth point of view, expressed in clear and readable language. The long extracts from case material and the bibliography, characteristic of American technical literature, are definitely helpful. Every social worker who has to place children should read this book; it will give her not only some useful practical hints but several new slants on this difficult work.

### CHOLESTEROL AND THYROID DISEASE

*A Clinical and Experimental Investigation of the Blood Cholesterol Content in Myxoedema and Other Conditions.* By E. H. Stokes, Ch.M., F.R.A.C.P. Sydney: Australasian Medical Publishing Company.

This small book is the reprint of an M.D. thesis, and though it adds little that is new to the subject, it will prove a useful text for reference for those interested in either cholesterol or diseases of the thyroid gland. The author found a mean serum cholesterol level above 250 mg. per 100 c.cm. in four groups of cases—myxoedema, xanthomatosis, Bright's disease, and diabetes mellitus. Estimation of the serum cholesterol is of great value in the diagnosis of myxoedema, as the level is invariably high in untreated cases and decreases on treatment. It is a better indicator of the disease than the basal metabolic rate because it can more easily be determined satisfactorily without the co-operation of the patient. The hypercholesterolaemia of myxoedema is not due to deficiency of plasma protein, and it is more closely related to the degree of myxoedema than the depression of metabolism. Neither the mucoid infiltration nor the excess of cholesterol is affected by stimulating the metabolism by nitrophenol or nitroresol, and there is no evidence that they are related to the low blood volume, which is probably a direct effect of the fall in the metabolic rate. The rise in the cholesterol of the blood and the mucinous infiltration of the tissues are difficult to produce by ablation of the thyroid in animals or man, but this may be largely a matter of duration of the disease. Certainly both symptoms quickly respond to thyroid medication, and the blood cholesterol is low in thyrotoxicosis.

### Notes on Books

The second edition of Dr. ALFRED PINEY's *Sternal Puncture* (Heinemann; 15s.) shows a great improvement both in text and in illustrations. It provides for the student a convenient review of information which is scattered over a wide literature. It will have less appeal for the professional haematologist, who may nevertheless have to admit that Piney's somewhat informal approach does seem to appeal to the beginner. And once the student has been successfully introduced to sternal puncture, he can go on learning out of the book of Nature. The pictures of the white cells are fairly uniformly good, but those of the nucleated red cells do not really do justice to the technique and would not be a great deal of help in the actual counting of marrow films. The bibliography might have been preceded by references to some of the general reviews of sternal puncture, such as Bodley-Scott's article and Schulten's monograph, which represent the high-water mark in text and figures

respectively. More detail would also have been welcome on the technique of sternal and bone-marrow transfusion, on which Dr. Piney has written interestingly elsewhere.

Sir COMYNS BERKELEY's *Gynaecology for Nurses and Gynaecological Nursing* has reached a ninth edition (Faber and Faber; 8s. 6d.). This very useful textbook first appeared in 1910. The subject-matter has been thoroughly revised for the new edition, parts have been rewritten and many paragraphs simplified. The author in his preface says he has always taken advantage of suggestions made by reviewers and acknowledges the help thus given to him. Acting on a hint in this column he has taken the opportunity to revise the index, and the main references now appear in heavy type. The appendix on blood transfusion has been remodelled and brought up to date, including a description of the Rh factor.

Dr. E. NOBLE CHAMBERLAIN has now revised his popular *Textbook of Medicine for Nurses* (Oxford University Press; 21s.) for a fourth edition. It continues to give up-to-date information on the medical disorders in a form which supplies nurses with all they need to know on causation, symptomatology, and treatment. It has a good index, a glossary, excellent illustrations, and some useful summaries in tabular form in the appendix. Yet with all this there seems to be something lacking—namely, an outlook which takes in the social aspects of medicine. Two pages on "causation of disease" at the very beginning of the book gives no idea at all of the environmental or psychological causes of disease. The author is too good a physician to be unaware of the new orientations in the medical world; perhaps his next edition will be extensively rewritten with this criticism in mind.

### Preparations and Appliances

#### SULPHANILAMIDE POURER FOR LOCAL USE

Mr. J. A. EAST, B.Sc., M.B., F.R.C.S., writes:

Mr. Hamilton Bailey and myself have been using the sulphaniilamide pourer described here with entire satisfaction. It is simple and efficient, and does not waste powder.

10 g. of sulphaniilamide powder are put in a bottle with a screw cap. The bottle has an inner cap with an eccentric hole in it, and is put in a carton and sterilized. The top and the bottom of the carton are held together with a strip of self-adhesive tape.

A. The sulphaniilamide pourer as supplied in a carton. The inside of the carton is sterile.

B. The carton is removed and the bottle is dropped on the sterile trolley. The screw cap is shown undone.

C. Top view of the bottle, showing the hole through which the powder comes out.

D. Sulphaniilamide powder is being poured on the wound.

When the powder is needed, an "unsterile" nurse opens the carton and drops the bottle without touching it on the sterile trolley. The surgeon can pick up the sterile bottle and use it. Whatever remains in the bottle is still sterile and can be used in the wards.

This pourer, with 5 g. of the powder as above, or containing 0.5 g. proflavine in addition, has been made for us by Genatosan, Ltd., of Loughborough. I thank Mr. P. Berry, medical superintendent of the County Hospital, Chatham, for permission to publish this account.

## SYSTEMIC TREATMENT IN SKIN DISORDERS

● Colloidal Calcium with 'Ostelin' produces marked improvement in many otherwise unresponsive skin disorders, especially if there is local congestion. In chilblains and in the allergic type of skin disease, urticaria, angioneurotic oedema and eczema, the effect is often rapid and almost specific. Irritation and swelling are relieved, and the reparative process is greatly enhanced.

Colloidal Calcium with 'Ostelin' is also a powerful general stimulant and is used in many conditions of ill-health to promote a subjective improvement in well-being.

Colloidal Calcium with Ostelin contains vitamin D (5,000 i.u. per cc.) with calcium in colloidal combination for injection.

Amboules 6 and 12 x 1 cc. Phials 30 cc.

## COLLOIDAL CALCIUM WITH OSTELIN

GLAXO LABORATORIES LTD., GREENFORD, MIDDX. BY ROY 3434

As a general antiseptic Collosol Argentum is rather more than equal to one per cent. phenol and is at the same time completely non-toxic and non-irritant. It is indicated in all types of inflammatory conditions of the ear, nose and throat. In cases of ophthalmia neonatorum Collosol Argentum Ophthalmic has become a standard treatment and has been indicated by some authorities as the best local remedy for cases admitted with gonorrhoeal ophthalmia. Full details of packings and prices available on application.

*Crookes'* COLLOSOL ARGENTUM

SATURDAY JANUARY 8 1944

## SURGERY OF HEAD WOUNDS

The present is a particularly appropriate moment at which to take stock of the results of specialized methods of dealing with war wounds. The North African campaigns with their varying problems of organization have terminated, and sufficient time has elapsed to allow of a useful follow-up. The campaigns of Europe are close upon us, in which it will be necessary to incorporate all the lessons that have been learnt in other theatres. The masterly account printed elsewhere in this issue, by Brigadier Hugh Cairns, of the development, organization, disposition, and activities of our neurosurgical units in North Africa and Libya gives an excellent review of the whole situation. The neurosurgeon in civil practice has long been regarded as unnecessarily slow and "finicky," and indeed has often been the butt of ridicule by the ignorant critic. That his peacetime technique could be successfully adjusted to the urgent demands of battle casualties was thought preposterous. But the end-results of neurosurgical specialists in civil surgery always justified the means, and now in battle-dress they have easily vindicated their methods. In the hands of a properly trained team equipped with suction, diathermy, etc., even the penetrating brain wound has been robbed of much of its terror; provided that operation is not delayed beyond 24 hours, and provided that the brain damage is not lethal, then prospects for recovery are bright and the risk of intracranial infection can be almost eliminated.

The strategical disposition of the units of Ascroft and of Eden and the results of their work have already been published.<sup>1</sup> To these figures Cairns adds those of Schorstein, of Sörgo, and of Cushing. The attainment of primary union in penetrating brain injuries is about the same in each series (65 to 70%), although deaths from intracranial infection occurred more frequently in the cases of Sörgo (30%) and of Cushing (36%) than in those of Ascroft (10.8%), and were least in Eden's (3.7%). The results obtained by the last-mentioned were due in part probably to the highly favourable combination of a special unit working in a forward area, with facilities for the air transport of operated and of less urgent unoperated cases back to a similar unit at the base. This was essentially a split unit with an air link. But, as Cairns points out, this disposition of the neurosurgical resources may not be the full explanation. The location of a battlefield—sited in one case in desert or sparsely populated and cultivated country, and in another case in a heavily populated and intensely cultivated area—may greatly influence the nature and the intensity of the flora of a wound. Elimination of infection from a wound sustained in France or in Russia

may be a much more difficult task than in a comparable wound in North Africa. That has yet to be determined. So far the published reports of the bacteriology of head wounds do not give much help in explaining the discrepancy between the results of neurosurgeons in North Africa and those of Sörgo and of Cushing. Pulvertaft<sup>2</sup> stresses the need for a standard technique for sampling the contaminating organisms of a wound, and the variability of the results of culture. He also raises the problem of sulphonamide prophylaxis. How valuable is it—if at all? Most surgeons believe in its efficacy, but Cairns rightly regrets that even now there is no unequivocal evidence of the value of prophylactic chemotherapy, local and general.

Penicillin was used in 23 cases of brain wounds of 3 days or older, and in some there was already pus in the brain, or a brain fungus. Only three of these patients died within the period of follow-up of 62 days. Although this is a small group, it seems clear that the effects of penicillin—when properly employed—are as dramatic in head wounds as in wounds elsewhere. Cairns sees fit modestly to state that the results are not unpromising. As the results of neurosurgeons operating early in the forward area are so good, penicillin may be found to be most beneficial in cases in which evacuation to a special unit is likely to be delayed. It seems probable that its use in full doses on a wide scale in the future campaigns will be of the greatest value in saving life and limiting tissue destruction by infection and the consequent disabling sequels. It is to be hoped that supplies will be ample, that the best technique for application will rapidly emerge, and that adequate control series are available so that the evaluation of results will be convincing.

The organization of neurosurgical units in the great campaigns imminent in Western Europe will be a difficult task, and doubtless the A.M.S. have their plans well laid, applying the lessons learnt so far. The problem is seen on a small scale in the comparison between the location of the units of Eden and of Schorstein; the former was in a "bottle-neck," while the latter was much less favourably situated to "tap" the flow of cases and to obtain segregation. If the principle of segregation continues to be accepted—and results amply justify it—then broadening of the front and widening of lines of communication will necessitate a great number of special units. At this point it is well to note the influence of air transport on this problem. Contrary to accepted neurosurgical teaching based on the experiences of the last war, it was found in North Africa that cases could be evacuated 2 to 3 days after operation without any deleterious effect. This is highly significant, and there may be two factors operating. Infection in France in 1914-18 was of a more fulminating character than that in the present series, and the deterioration ascribed to transport may in fact have been due to latent infection, possibly aggravated by transport. The other factor, probably the more important, is the nature of the transport, and in Africa air transport was employed, with its correlated speed, comfort, and lack of jolting as compared with road and rail. Therefore if sufficient trained personnel were available, the successful solution might be

<sup>1</sup> *Lancet*, 1943, 2, 659.<sup>2</sup> *Lancet*, 1943, 2, 1.

found in a multiplication of units of Eden's type—a split unit with an air link.

The alternative, as Cairns indicates, is for the general surgeon to deal with all but the more difficult wounds. If the general surgeons are to do this work successfully, then it is essential that they receive proper training and equipment, and it is equally essential that they should be convinced individually of the need for acquiring the small but important details of procedure termed technique. To quote Eden: "There is no doubt that the surgeon who first operates on an open brain wound makes or mars it. There is no useful first-aid operation." He and Ascroft give all the necessary details, and Ascroft rightly emphasizes the need for painstaking care over the minutiae which seemingly waste time: "Time is saved by not skipping the preliminaries. Careless placing of the patient on the table, niggardly shaving, and indifferent arrangement of the drapes all make for slow and wearisome operating." And this care is as necessary for scalp wounds as for penetrating injuries. That this technique justifies itself is borne out again and again in civilian and in military surgery, and has often been brought to notice. Eden obtained primary union of scalp wounds in 97% of cases, but this was obtained in only 50% of similar cases passed to him after operation by general surgeons. The respective figures for wounds with dura intact were 84% and 12% and for brain wounds 71% and 25%.

In order to undertake his share of the work the general surgeon should be given adequate opportunity for training. One cannot help feeling that in this direction—at any rate so far as neurosurgery is concerned—the A.M.S. have shown an incredible lack of foresight and of imagination during the last three years. A few courses in neurosurgery of warfare have been held, which can have been attended by only a minute fraction of Army surgeons; and such courses, good as they may be, can never compare in value with the first-hand experience afforded by living in a special centre for, say, a month. The great potential reservoir of tuition presented by the E.M.S. special head centres has been virtually untapped. It should in all fairness be made clear that the E.M.S. neurosurgeons have been clamouring for years, without response, for this opportunity of giving instruction to military surgeons.

If instructions are issued that the general surgeon shall perform only a "first-aid operation" as far as the dura, it is important that opinion should now be crystallized as to the best procedure. Should the superficially excised wound be left open as recommended by Ascroft? Or should it be closed, for fear that final operation may be delayed more than three days? Many secondary débridements were performed after a considerable interval, with remarkable recoveries in cases in which the wound had been closed at the primary operation in the forward area. Local application of penicillin may provide a solution to this question, and one wonders whether the local application of powdered proflavine in this type of case has had due consideration. Its use has been condemned, but the comparison of its necrotizing effect upon the experimental animal's brain with its effect on potentially infected and grossly traumatized brain seems hardly fair (Russell<sup>3</sup>).

<sup>3</sup> *Lancet*, 1943, 2, 580.

There is still divergence of opinion about certain other operative details. In practically all the North African cases the wound was drained for 24 to 48 hours, especially when the operation created a deep cavity in the brain. The dural tear was never repaired except in those few cases in which the wound also involved the paranasal sinuses. Sörgo drained only those cases in which operation was delayed more than 24 hours. He advocates closing the dural defect, if necessary with a fascia lata graft, and dural closure may have an important influence upon the incidence of residual brain infection. If, as Cairns suggests, infection develops first superficially in the scalp, and then spreads inwards, closure of the dura would be an advantage. On the other hand, it is clear from Eden's and Ascroft's papers that they would consider such a procedure liable to accelerate brain infection. Perhaps a combination of both methods will prove advantageous—dural closure, with a drain into the cavity between the stitches of the graft. If the insertion of a graft diminishes the amount of mesoblastic scar invasion of the brain, and thus lessens the incidence of epilepsy, then this addition to the operation would justify itself.

There is no doubt that the neurosurgical organization in North Africa and Libya has paid valuable dividends, and it is a pleasure—and one hopes not a presumption—to comment here upon the high standard of case-recording maintained under the pressure of action. Such records are the life-blood of worth-while follow-up statistics. Those who have been privileged to care for cases invalided back to this country have perused with interest and with amazement the detailed and excellent notes. It is the signature of efficiency.

### AETIOLOGY OF CONGENITAL PYLORIC STENOSIS

Congenital pyloric stenosis is not, perhaps, a common disease, but it is common compared with most hereditary abnormalities. There are a number of striking facts about its aetiology. In the first place boys are much more often affected than girls. Secondly, there seems to be a strong tendency for those affected to be first-born children. For example, Still<sup>1</sup> found that 48% of a series of 400 were first-born. Moreover, it is a congenital abnormality highly dangerous to life which yet can be treated with much success. Cockayne and Penrose<sup>2</sup> in an admirable recent investigation found that out of 221 children treated, the families being visited after an average lapse of 6½ years, 170 were alive, and in most cases appeared to be perfectly healthy.

The difficulties of investigating the aetiology of a condition of this type are not small. To take one point—the supposed susceptibility of the first-born child—it is evident that hospital data alone can provide little evidence because so many of the children with congenital pyloric stenosis are not only the first in their families but also, at that time, the last. In order to study this and other points thoroughly, Cockayne and Penrose decided to attempt to follow up after the lapse of ten years the families of 434 consecutive cases (mostly treated at St. Thomas's Hospital and Great

<sup>1</sup> *Lancet*, 1927, 2, 795, 853.  
<sup>2</sup> *Ohio J. Sci.*, 1943, 43, 43.

Ormond Street Hospital for Sick Children). It is not surprising to learn that it did not prove possible to visit more than 212, and that the interval was not, on the average, more than 6½ years. Nevertheless, valuable data have been collected and the results are remarkably interesting.

There is no doubt about the hereditary nature of this abnormality or that it depends upon a recessive gene. There is a significant excess of consanguineous marriages among the parents, as would be expected in a relatively rare recessive condition. Though the familial incidence is much smaller than the expected 1 in 4, it is real. Evidently, however, the susceptible child—that is, the child bearing the abnormal gene pair—is not always affected. Cockayne and Penrose are able to show that the additional factors determining the appearance of the abnormality are those previously suspected—viz., sex and being a first-born child. Affected boys are six times commoner than affected girls. The question of primogeniture is much more difficult to study. In the key paper on the calculation of family size Greenwood and Yule<sup>2</sup> showed that the families selected by reason of the presence of one abnormal member give an erroneous impression of size, and so, if appropriate allowance is not made, first-born children will always appear to be unduly numerous among affected persons. Even the method of Greenwood and Yule requires further modification when the interval, as in this case, between the birth of the affected child and the tabulation of family number is relatively short. Making the necessary allowances, Cockayne and Penrose leave little doubt that primogeniture is indeed an important factor. It is a good example of the difficulties of human material and of how an extensive investigation and refined statistical methods are often needed to settle a problem which at first sight seems simple. Another point about family order is that it is closely associated with maternal age; hence it is far from easy to determine which of these two factors is actually responsible. Penrose<sup>4</sup> devised an ingenious method for discriminating between the two possibilities. He then showed that in the classical instance of mongolism it is maternal age that is important and that order of birth is without effect. In congenital pyloric stenosis the reverse is shown to be true. Being a first child is what counts and not the age of the mother.

The results of this investigation are plain and leave little room for doubt. The underlying cause of congenital pyloric stenosis is the possession of a pair of abnormal genes, one received from each parent. Should the recipient chance to be a boy and first-born, he will almost certainly have this abnormality. In other words, if the first child of carrier parents is a boy, his chance of being affected is the Mendelian 1 in 4, as in albinism or amaurotic idiocy. Subsequent children who receive the two abnormal genes, or any daughter, even if she is first-born, are more likely to be normal than affected. This is a point of considerable practical importance. Cockayne and Penrose found that some parents had limited the family after the patient's operation because of the fear that another child might have to undergo the same treatment; yet the chance of a subsequent child being affected is not more than one in twenty.

## DEATH OF DR. ANDERSON

We have to announce with deep regret, which all members will share, that Dr. G. C. Anderson, Secretary of the British Medical Association, died in hospital on the night of January 1 from heart failure following the attack of coronary thrombosis which laid him low on October 23. From the day he joined the staff at headquarters in 1919 he gave himself with abounding energy and enthusiasm to the Association and the profession, and in their service he wore out a fine physique. Our personal loss cannot be measured in words, but a memoir of Dr. Anderson, with some tributes from Officers of the Association past and present who have had very close relations with him, appears in this week's *Journal*.

## HEAT IN THE TREATMENT OF SHOCK

In the last war the shocked wounded were vigorously heated because they were cold. The application of radiant-heat cradles became an accepted principle of treatment. It was claimed, as a result of heat therapy, that the pulse improved in volume. Between the two wars, however, accumulated evidence cast doubts on the wisdom of heat in the shocked patient. Extensive studies by Lewis's school on the blood vessels of the skin showed that heat produced a great increase in blood flow through the skin, and that the vessels of the hand took a very large share of this increase. The skin of the human hand is, in fact, an important temperature regulator, similar to the ear of the rabbit. It would be surprising, therefore, if the application of excessive heat did not bring about an "improvement" in pulse volume at the wrist. We must question, however, whether an increased blood flow through the skin is a desideratum in shock, where the blood pressure is low as a result of acute loss of blood. Bazett<sup>1</sup> has estimated that 500 c.cm. of blood may be diverted into the warm skin. In addition to the increased flow through the skin, blood flow through muscle is also increased by heating (Barcroft and Edholm<sup>2</sup>).

Taking cognizance of these considerations, Blalock and Mason<sup>3</sup> in crude but striking experiments on dogs showed that excessive heat was harmful and accelerated death. Cleghorn<sup>4</sup> has demonstrated in careful and painstaking studies on dogs bled to a blood-pressure level at which the expected mortality was 40% that the optimum external temperature is 72° F. At this temperature 18 out of 22 animals survived; at an external temperature of 95° F. only 1 out of 14 survived. Man and dog, however, are different species, and more observations are required in normal human subjects and in patients suffering from different types of "wound shock." Brown, Evans, and Mendelssohn<sup>5</sup> mentioned a slight fall of blood pressure on the application of radiant-heat cradles. Kay, in our current issue, now demonstrates in "normal" convalescents a fall in arterial pressure and a rise in venous pressure in response to heating. These effects can both be explained by peripheral vasodilatation. Such observations, however, mark only the beginning, and much remains to be done. Is the cardio-acceleration on heating a direct temperature effect, or does it result, as Kay suggests, from increased venous return exciting a Bainbridge reflex? Are rises of venous pressure in the peripheral veins of man paralleled in magnitude by changes in pressure in the right auricle? If the increased peripheral circulation is part of a general

<sup>1</sup> *J. Amer. med. Ass.*, 1938, 111, 1841.

<sup>2</sup> *J. Physiol.*, 1943, 102, 5.

<sup>3</sup> *Arch. Surg.*, 1941, 42, 1054.

<sup>4</sup> *Canad. med. Ass. J.*, 1943, 49, 363.

<sup>2</sup> *J. statist. Soc.*, 1914, 77, 179.

<sup>4</sup> *Ann. Eugenics*, 1934, 6, 108.

increase in minute volume flow, at what stage of reduced blood volume does heating cease to improve the general circulation and increase the peripheral flow only at the expense of vital internal organs?

The study of such circulatory reactions in injured and normal man not only will improve our management of the injured but will add richly to our knowledge of human physiology. The techniques of study developed by Cournand and his colleagues<sup>6</sup> show the way in which these problems may be approached: their bold, brilliant, and apparently safe technique of intracardiac catheterization seems to open a new era in the research study of human cardiodynamics. Research by this method in severe shock would sweep away much doubt and obscurity. Meantime, as a practical policy in the treatment of shock, we must accept the evidence that overheating is harmful, and agree that a comfortable external temperature environment is probably best.

### WAR IN THE NURSERY

War nurseries are now in the limelight of controversy. Clearly all is not well when an authority such as Dr. Helen Mackay, after careful investigation, has to report a high incidence of infection and a low incidence of happiness. Although this statement has evoked protest from an experienced nursery teacher, there is ample evidence, from other good teachers and nurses, of grave distress among their children. Unhappily for the "under-fives," the characteristics of their age make them peculiarly sensitive both to any disruption of the family situation and to the fact of war. Children are born as little savages whose destructive and aggressive impulses are primarily diverted to social ends through love relationships, formed first by intimate contact with the mother, and extended in widening circles to others within the home until, upon the pattern so established, contacts are made with the larger world of human society. In the years from 2 to 5 the battle between love and primitive impulse is at its height. Dr. E. Benjamin<sup>7</sup> describes this as the "Age of Resistance." Winnicott, Bühler, Isaacs, Bowley, and others all note the turbulent characteristics of the age. Anna Freud, in her report of the admirable Hampstead nurseries, quotes a saying, half-joking but significant—"There is continual war raging in the nursery"—with reference to the violently aggressive tendencies normal in the early years. Such tendencies are the growing-pains of the parent-child relationship. In the course of natural development they are outgrown if wisely handled within this relationship. Separation from home cuts at the root of the little child's intrafamily situation which is the basis of his social development. No longer has he the incentive to sacrifice his unclean habits, his tempers, and general devilry that he may secure his mother's love. This he has always feared to lose, and now in his immature judgment it is already lost, or why should she have abandoned him to others? In such a desperate situation he must either withdraw into anxiety and depression, or in self-preservation, as it seems, he must rage more furiously.

At the present time there is the added danger that the destructive impulses let loose in war may serve to fan the flame of aggression natural to the nursery age. Bombing, killing, burning are all accepted by adults as meritorious when meted out as retribution to the wicked enemy. These are the terror-making fantasies of early childhood come true, provoking further fear and reactive resistance to a world so dangerous. It is small wonder that the nursery

situation is a difficult one, that children are often unhappy, and the nerves of staff strained to breaking-point. Some notable nurseries, which lay much stress on mothering their temporary orphans, have proved that in many cases it is possible to overcome difficulties, but these must be recognized to be resolved. If they are not, asocial or anti-social behaviour remains as a fixed protest. The "Age of Resistance" may thus be prolonged to adolescence or adult life in the form of bitterness, irresponsibility, or delinquency.

### NO NEWS BUT THE OLD NEWS

A letter in the *Times* of Dec. 31 reminded us that 1943 saw the centenary of the publication of the *New England Quarterly Journal of Medicine and Surgery*, which was edited by Charles E. Ware, M.D., and Samuel Parkman, M.D. This journal was published in Boston and came to an end after a year. In its April issue appeared the article by Oliver Wendell Holmes entitled "The Contagiousness of Puerperal Fever." This had previously been read before the Boston Society for Medical Improvement. Tales from medical history are always worth retelling, even one so familiar as the story of puerperal fever. As the exciting causes of puerperal fever have been tracked down in detail only recently, it is of interest to note that nearly 101 years ago Oliver Wendell Holmes began his paper thus: "In collecting, enforcing and adding to the evidence accumulated upon this most serious subject, I would not be understood to imply that there exists a doubt in the mind of any well-informed member of the medical profession as to the fact that puerperal fever is sometimes communicated from one person to another, both directly and indirectly." A little later in his paper he states his thesis in this way: "The practical point to be illustrated is the following: *The disease known as Puerperal Fever is so far contagious as to be frequently carried from patient to patient by physicians and nurses.*" (The italics were his.)

Semmelweis, who shares with Holmes what one might call the honours of puerperal fever, became an assistant in the first obstetric ward of the Allgemeines Krankenhaus in Vienna in 1846, and in 1847 published his work on the aetiology of epidemic puerperal fever. Garrison, in his *History of Medicine*, pays due tribute to Semmelweis and Holmes, and also to Charles White of Manchester, but makes no mention of the work of Dr. Alexander Gordon of Aberdeen, so generously acknowledged by Holmes in his original paper. Dr. Gordon published a treatise on puerperal fever in 1795. Evidently his observations had been, as Holmes points out, "occasionally copied into other works." It may therefore be of interest if we follow Oliver Wendell Holmes's example of giving exact quotations from Dr. Gordon's treatise:

"This disease seized such women only as were visited, or delivered, by a practitioner, or taken care of by a nurse, who had previously attended patients affected with the disease."

"I had evident proofs of its infectious nature, and that the infection was as readily communicated as that of the small-pox or measles, and operated more speedily than any other infection with which I am acquainted."

"I arrived at that certainty in the matter, that I could venture to foretell what women would be affected with the disease, upon hearing by what midwife they were to be delivered, or by what nurse they were to be attended, during their lying in: and, almost in every instance, my prediction was verified."

Modern workers have in effect done little more than dot the i's and cross the t's of this story, by stating in exact terms just what the infection is.

## THE MODERN TREATMENT OF GONORRHOEA IN THE FEMALE\*

BY

T. E. OSMOND, M.B.

*Brigadier, Consulting Venereologist to the Army*

Gonorrhoea in the female is similar in many respects to that in the male, but in some ways is of considerably more importance, since many women suffer from the disease without knowing it and therefore probably convey it to a greater number of people than they would otherwise. Incidentally, too, gonorrhoea not only may infect the eyes of the child during its passage through the birth canal but is also a very common cause of sterility, mainly as a result of salpingitis causing occlusion of the Fallopian tubes. In the case of gonorrhoea in a married woman consent should be obtained to tell the husband not only in order that he may be examined and, if necessary, treated, but also to avoid the risk of marital infelicity should he find out accidentally; in the case of a girl under 21 the parents should be told if circumstances appear to demand it. Such action is likely to prevent difficulties arising later, especially if the girl should become engaged to be married. It is a great mistake to adopt a policy of secrecy, and all those who are, or are likely to be, involved should be told in confidence.

### Diagnosis

The signs and symptoms may be much the same as in the male—that is, a discharge of greenish-yellow pus accompanied by pain on micturition—but often the latter is entirely absent, and it must be remembered that discharges of various kinds are regarded by many women, especially multiparae, as hardly abnormal.

Place the patient in the lithotomy position and separate the labia majora; note any discharge from the vulva, vagina, and urethra, any swelling or inflammation of Bartholin's glands, and any discharge from their ducts. Swab the vulva clean and dry; pass the first finger of the gloved left hand into the vagina and draw it forward along the floor of the urethra; by this means any discharge will be brought to the urethral orifice; near this latter look for any discharge from Skene's ducts. Next pass a speculum (Cusco) into the vagina and open it to bring the cervix uteri into view; note any erosion of the external os; clean the cervix and surrounding parts with a swab—dry or soaked in weak alkaline solution if there is much mucoid secretion—and note any discharge coming from within the canal. Take specimens for smear and culture from within the urethra and cervical canal and from any discharge from Bartholin's ducts. Examine uterus and adnexa bimanually to ascertain if pelvic inflammation, especially salpingitis, is present.

In cases of acute gonorrhoea gonococci are easily demonstrated, but in chronic cases they are often difficult to find; if gonococci are not in evidence at first, further examinations should be carried out at short intervals. Gonococci are most likely to be found *immediately* after a menstrual period (some clinicians recommend examination *during* a period). Such examination should be repeated monthly, if necessary for three months, before gonorrhoea can be excluded. It is most important to take cultures as well as smears, since the flora of the vagina are very numerous and varied and it is often quite impossible to say whether gonococci are present or not from the examination of smears alone. In chronic cases a gonococcal complement-fixation test (G.C.F.T.) is often helpful, but in acute cases this will usually be negative unless the disease has been present for some time or complications are present; a positive reaction is valuable, but a negative one does not exclude gonorrhoea.

In acute cases examination of the urine, as in the male, will frequently reveal a haziness due to pus if the patient has not passed water recently; specimens may be made from centrifuged urine for bacteriological examination. In chronic cases diagnosis is often very difficult, and can be established only by repeated careful examination and taking of specimens; the latter are best taken with a sterile platinum loop or a dressed Playfair probe. No lubricant should be used when passing a

speculum, since this may inhibit the growth of gonococci in cultures. In all cases it is wise to look for trichomonas vaginitis at the same time, as this is a very common accompaniment of gonorrhoea and, if present, is apt to delay cure unless vigorously treated.

### Treatment

Early acute cases usually react well to chemotherapy, but old-standing chronic cases, especially where the cervix uteri and perhaps the pelvic organs are involved, are often very difficult to cure. The general practitioner will do well to remember this and not undertake the treatment unless he feels thoroughly competent to do so. If the patient is married it is most important that the husband should be examined and, if necessary, treated; if husband and wife are both infected they should obviously both be treated, as otherwise repeated re-infection may occur. In any case it is the moral duty of any physician treating a case of communicable V.D. to endeavour to trace the source of the infection and bring him or her under treatment.

**General Treatment**—This should be on the same lines as for males; rest during the acute stage and careful personal hygiene are most important.

**Chemotherapy**.—Sulphathiazole 4 g. a day (1 g. four times a day) for 5 days—total 20 g.—will cure the great majority of acute cases, and the fluid intake should not be less than 6 pints. Where the patient can be kept under the physician's eye—e.g., in hospital—a rather higher dosage may be employed. Bolton (1943) recommends 7.5 g. the first day and 5 g. daily for the succeeding four days—total 27 g., the patient being kept in bed during the period of chemotherapy. In either case if the first dose is given early in the morning and the last dose late in the evening there is no need for one during the night. Should a second course be necessary an interval of seven days should be allowed to elapse and preferably the type of sulphonamide changed—e.g., to sulphadiazine or sulphapyridine; a blood count should be done before starting a second course. Intolerance and its treatment are the same as in males. The urine should be rendered alkaline with sodium bicarbonate to prevent haematuria, and if symptoms are acute tincture of hyoscyamus minimis 20 and tincture of belladonna minims 5–10 three times a day may be prescribed.

**Local Treatment**.—In acute uncomplicated cases this is rarely indicated beyond that necessary for personal hygiene—i.e., frequent hot baths, to which alkalis may be added, and the keeping of the affected parts dry and clean. In chronic cases, and especially those which do not react to the sulphonamides, irrigation of the urethra and bladder may be carried out as in the case of males; but routine vaginal douches are to be deprecated, dry or moist swabbing being preferable. It should be remembered that in adult females vaginitis is not a prominent lesion, the brunt of the disease falling on the urethra and cervix uteri. The vagina and cervix should be swabbed, dry or with a mild antiseptic, using a Playfair probe dressed with cotton-wool, and, following this, the whole surface should be dusted with powder applied by means of an insufflator. Cervical erosions should be treated, after clearing the secretion away, with weak alkali, with topical applications, applied by means of a Playfair probe, care being taken not to pass the internal os. Probably the best substance is glycerin, and this may be used neat or in the form of glycerin of borax or glycerin of ichthylol 5%; other applications recommended are mercuriochrome 1%, picric acid 1% in spirit, and acriflavine 0.5 to 1%. These applications should be carried out daily in subacute cases and once or twice weekly when the condition is chronic, ringing the changes on the various preparations. Cystic swellings (ovulae nabothi) are treated by puncture. As an adjuvant to chemotherapy the insertion of two tablets of acetarsol at bedtime is very helpful, or the vagina may be insufflated daily with this drug in powder form or with powdered sulphanilamide; local treatment should be carried out by the nurse or the medical officer himself wherever possible. Sulphonamide-resistant cases often call for pyrotherapy, applied by means of a fever cabinet or protein injections (e.g., T:A.B. vaccine) as described for males.

### Complications and their Treatment

Many of these react well to chemotherapy, but a closed focus—e.g., a Bartholin's abscess—should be drained. When serious complications occur it is wise to refer the case to a specialist

\* Written by request in continuation of the article on gonorrhoea in the male which appeared in the *Journal* of July 17, 1943 (p. 72), and for the same reasons.

if they do not clear up under chemotherapy. When chemotherapy fails the following measures may be adopted:

1. *Skenitis*.—This is an inflammation of the gland ducts opening on either side of the urinary meatus; the ducts should be destroyed with the electric cautery or fused silver nitrate, or injected with tincture of iodine, 10% silver nitrate, or 10–20% mercurochrome.

2. Urethral caruncle, which forms at the meatus, should be excised or cauterized.

3. *Bartholinitis, or Bartholin's Abscess*.—The gland should be dissected out or the abscess laid open freely.

4. *Salpingitis, Oophoritis, and Pelvic Peritonitis*.—If acute the patient should be put to bed in the Fowler position and treated on expectant lines; as soon as the acute symptoms have passed off, hot vaginal douches may be given once or twice daily, and, when the chronic stage is reached, two or three times a week. Operation is rarely called for if the infection is purely gonococcal; if in doubt call in a gynaecologist.

5. *Metritis and Endometritis*.—In the acute stage treat as for salpingitis. When acute symptoms pass off, treat as for cervicitis; dilatation of the cervix and the insertion of a glycerin drain are often helpful.

6. Other complications, arthritis, etc., are dealt with in the same way as in males.

7. *Trichomonas vaginitis*, which, as has been said, is a very common accompaniment of gonorrhoea, should be treated from the first; it is troublesome to cure and very apt to relapse. Its presence should be suspected in those cases of gonorrhoea which fail to clear up in the ordinary way.

#### Tests of Cure

These are even more essential than in males, because conclusive evidence of cure is so much harder to obtain. Gonococci have a way of disappearing under treatment and reappearing after treatment has been stopped, more especially at the menstrual periods; apparently they may lie dormant in the endocervical glands for very long periods. One or two tests should be carried out at four-day intervals following completion of treatment, and then monthly for at least three, and preferably six, months before the patient is discharged as cured. These latter examinations should be carried out immediately after a menstrual period, since it is at this time that gonococci, if present, are most easily detected. The following procedure is recommended:

1. Clinical examination, including smears and cultures from the vagina, urethra, Bartholin's ducts, and the endocervix. Specimens should also be taken from the rectum, as this is often infected in females. The importance of cultures cannot be overestimated, but it is essential that a suitable medium be employed.

2. Examination of vagina and cervix through a speculum.

3. Examination of the urethra through a urethroscope.

4. Bimanual examination of the pelvic organs, including uterus, tubes, and ovaries.

5. G.C.F.T.—This is of particular value when the disease has been chronic, if there have been complications, or if a previous, ositive result has been recorded.

During the period of observation in the case of a married woman, if intercourse takes place the husband should employ a sheath, not only for his own protection but in order that impregnation should not occur. A woman should not allow herself to become pregnant until the fact of cure has been established with as great a degree of certainty as possible.

#### Pregnancy and the Puerperium

The treatment of gonorrhoea during pregnancy is similar to that already described, but it is important to exercise the greatest gentleness both in taking specimens and in carrying out instrumental treatment in order to avoid the risk of inducing an abortion or miscarriage. Douching should be avoided and, owing to the fact that the discharge is often profuse, care should be taken to keep the genital area dry with dusting powder to avoid excoriation. Sulphonamide drugs are not contraindicated—pregnant women tolerate them well—but anything likely to cause a general reaction should be avoided. When labour starts an endeavour should be made to cleanse the birth canal, as it is particularly important to avoid risk of infection of the eyes of the infant; they should be treated thoroughly as soon as it is born.

If fever occurs during the puerperium it is possible that the gonococcus may be responsible; if the interior of the uterus is involved a catheter should be passed, with aseptic precautions, up to the fundus and glycerin or glycerin and iodine instilled

through it. The patient should of course be kept in the Fowler position.

#### Gonorrhoea in Female Children: Vulvovaginitis

The vagina of the adult is lined with stratified epithelium and is therefore relatively resistant to the gonococcus; but that of the young female is lined with delicate columnar epithelial cells, and is very susceptible to infection. Infection may occur at birth direct from the mother's secretions or at any time up to puberty through the medium of infected articles such as towels, napkins, underclothing, baths, and instruments. Criminal assault is a not uncommon cause.

*Signs and Symptoms*.—In the case of young females the brunt of the attack falls on the vagina, though the urethra almost invariably and the cervix frequently are also involved; the vulva is usually red and inflamed, and may be excoriated; discharge is often profuse and there is considerable discomfort. Specimens for bacteriological examination should be taken as in the adult, but it will often be impossible to pass a vaginal speculum; in such cases a urethroscope as used for the adult male is most useful for examining the interior of the vagina and the cervix. It must be remembered that the majority of cases of vulvovaginitis are due to causes other than the gonococcus: these include other organisms (staphylococci, streptococci, etc.), parasites, and trauma; a diagnosis of gonorrhoea should therefore not be made unless the gonococcus is demonstrated. The anal canal and rectum are commonly involved, and these should be examined carefully in all cases.

*Treatment*.—It should be remembered that this disease is extremely contagious and may easily spread rapidly through a community of young girls; the patient should therefore be isolated and the communal use of toilet articles forbidden; all contacts should be examined and every endeavour made to find and treat the source of the infection. Chemotherapy is the treatment of choice, and the disease usually reacts well. Sulphathiazole should be prescribed in dosage according to age and weight (0.5 g. per 15 lb. of body weight)—i.e., one-quarter to half a tablet three times a day in early life, rising to one tablet three times a day at the age of about 5 years; the usual precautions as to side-effects must be taken. Frequent hot baths and scrupulous cleanliness of the affected parts—keeping them as dry as possible—are indicated; but local treatment should be avoided so far as is possible, as this has a bad psychological effect and may lead to masturbation. Where indicated, local treatment is similar to that for adults, the cervix being treated through a urethroscope. When other methods fail an attempt to encourage the formation of resistant epithelium may be made by the administration of ovarian hormones; but this is a matter for the expert. Cases of vulvovaginitis are notoriously difficult to cure, and are very liable to relapse; treatment should therefore be continued, except in those cases which react well to the sulphonamides, for some time after all gonococci have disappeared, and tests of cure should be carried out over considerable periods, particular attention being paid to the rectum.

#### THE ORDER OF ST. JOHN

Two reports, the covers of which bear the white eight-pointed cross of the Order of St. John, have been received from the Chancery of the Order in the ancient gateway of St. John's priory at Clerkenwell. One of them is a report of the Chapter-General of the Order on the progress of its various modern foundations—namely, the St. John Ambulance Association and the St. John Ambulance Brigade at home and over-seas; the other gives an account of the ophthalmic hospital of St. John in Jerusalem, the city where the original Order was founded during the first Crusade. There were critics years ago, both before and after the incorporation of the English branch of the Order by a charter granted by Queen Victoria, who described it as sham-Gothic and absurd, but every critic must by now have been won over by the disciplined humanitarian work of this venerable institution.

#### Work of the Association and Brigade

The St. John Ambulance Association issued just upon 120,000 first-aid certificates last year and nearly 25,000 certificates for home

nursing. It organized a very large number of classes for the instruction and examination in first aid of members of the Home Guard and of the Civil Defence services. Over 100,000 of those who hold the certificate present themselves for re-examination yearly. The current textbook of the Order, since its appearance in 1938, has reached a circulation of 2½ million copies. The Brigade, too, is flourishing, with an increase during the last year in this country alone of 20,000 members, bringing the total to 167,000. In the Provinces, particularly in the smaller towns, the casualty services are largely manned by St. John's personnel, assisted by the British Red Cross Society. While their help in dealing with casualties is only occasionally required, they must always be ready to answer a call. Another activity of the Brigade is the motor ambulance service, which continues to render valuable assistance to the civil population. The number of cases conveyed in a year runs into six figures. The Brigade enlists the services of 3,000 surgeons, many of whom, in addition to their Brigade duties, are also serving in Home Guard units and at first-aid posts. We can well believe that many local authorities who are responsible for the posts regard those which are under the control of the Brigade surgeons as the most efficient in their area.

It is just fifty years since the first division of the Brigade was established overseas—in New Zealand—and now there are reports from all the Dominions and from many of the Colonies of encouraging progress, while Australia has just attained the dignity of a "commandery." In Bombay members of the Brigade put in 75 hours of consecutive duty when a large building collapsed causing many deaths; they rendered first aid to 342 persons. A special word should be said about the members of the Brigade serving in Malta, who have had to stand the strain of 2,000 air raids.

#### Ophthalmic Hospital In Jerusalem

The ophthalmic hospital in Jerusalem was founded sixty years ago, and last year it had 20,000 new patients and the total number of consultations was 125,000. In addition to its work in the ancient city it is responsible for ten ophthalmic clinics attached to Government hospitals in outlying centres in Palestine, from Acre and Safed in the north to Gaza and Beersheba in the south. These are staffed by medical officers and nurses, the latter obtaining their ophthalmic training during a four-months course at the hospital. The Government in Palestine is taking steps to minimize eye disease by means of propaganda films which are sent through the villages, and in these the value of the hospital service is given prominence. It is mentioned by the warden, Dr. Norman Manson, that the incidence of trachoma among the out-patients of the hospital was 89.3% last year, but that the neglected and virulent type of trachoma which was common even ten years ago is not often seen. Acute conjunctivitis continues to take its yearly toll in the summer epidemics that ravage the Near and Middle East. Excellent work is being done by the hospital, and a recent visit by the Duke of Gloucester, the Grand Prior of the Order, gave the workers much encouragement.

#### GRANT-IN-AID PLAN FOR HOSPITAL SERVICE

King Edward's Hospital Fund for London has sponsored a Hospital Service Plan whereby people of moderate means, in return for their subscriptions, may receive grants-in-aid towards the payment of hospital charges and medical fees. A non-profit-making company—the London Association for Hospital Services, Ltd.—has been created to operate the plan.

The method depends upon a system of monthly, quarterly, or annual subscriptions, or, if preferred, by arrangement with employers, of deductions from pay. Subscribers are required to undertake payment of subscription for one year, after which membership is renewable annually. Grants are made towards the cost of six weeks' treatment received by the subscriber or by his or her dependants up to a total of one hundred guineas in any one membership year, and the eligibility for such assistance begins six months after the effective date of enrolment. Applications are invited from all persons up to sixty years of age, regardless of their rate of income, provided that they live or are employed within the metropolitan area. The rate of subscription varies according to the number of dependants. For the single subscriber it is 4s. 4d. monthly, and for the subscriber with four dependants it is a maximum of 8s. 9d. Only one adult dependant may be registered by each subscriber. A schedule of rates of repayment for nursing-home charges, fees of physicians and surgeons, anaesthetist's services, and other forms of investigation and treatment is published, but a considerable number of classes of treatment—including, for example, primary consultation fees, maternity treatment, and medical cases normally treated by the patient's own doctor in the surgery or at the patient's home—are excluded from liability. It is agreed that full cover is the desirable ideal, but until that can be undertaken the present grant-in-aid scheme is believed to fill a distinct need.

The scheme has been prepared with the full approval of the voluntary hospitals and of the British Medical Association, whose secretary is a medical member of the council of management. There are, naturally, a number of conditions attached to an insurance scheme of this nature, but they bear every evidence of having been carefully thought out so as to afford as much benefit to the insured person as possible. Particulars can be had from the offices of the London Association for Hospital Services, 10, Old Jewry, E.C.2.

#### FURTHER INCREASES IN NURSES' PAY

Publication of the second report of the Rushcliffe Committee on Nurses' Salaries means that the salaries of all nurses in England and Wales except those in mental hospitals have now been reviewed. (The recommendations affecting hospital nurses were noticed in these columns on Feb. 27, p. 264, and for midwives on Aug. 21, p. 242.) The latest report covers nurses in the public health services, in residential and day nurseries, district nurses, and male nurses, and like the earlier one recommends national salary scales to apply throughout England and Wales, which will in most cases mean substantial increases.

Nurses in the public health services include health visitors of all grades, school nurses, tuberculosis visitors, and nurses in V.D. clinics, and the proposed new salaries are: for a health visitor, £270, rising by £10 a year to £360; superintendent health visitor, £360 to £550 according to the numbers supervised; tuberculosis visitor, £270-£360; school nurse, £220-£310; nurse in V.D. clinic, £250-£320.

The committee concurs in the view long held by the medical profession that the pay of district nurses has never been commensurate with their responsibility, and it proposes that a State-registered district nurse living in a district nurses' home shall receive £120 a year, rising by £10 to £180, the total value of salary and emoluments to be £220-£280. A similarly qualified district nurse living at home or in rooms should receive salary and emoluments of £230-£300. The village nurse-midwife (S.C.M.) living in a district nurses' home is to receive £100-£170 (total value of salary and emoluments £200-£260), and if she lives at home a total of salary and emoluments of £210-£270.

As regards nurseries, the committee has confined itself to recommendations affecting State-registered nurses employed in day or residential nurseries, and for these the new salaries suggested are £170, rising by £10 to £240, with emoluments of £100 in addition, for the matron of a residential nursery housing 40 or more children and having students in training. Where no training is given the salary should be £150-£220, with the same emoluments. A non-resident matron should receive £195-£305 and her deputy £165-£255. The salaries of male nurses, who number some 2,000, mostly employed in London, will be £7 14s. 6d.-£9 10s. 6d. a week for a qualified senior tutor, £6 5s. 6d.-£7 5s. 6d. for a superintendent nurse, and £5 0s. 6d.-£5 15s. 6d. for a staff nurse.

Other recommendations of the committee concern uniform, holidays, and sick pay. These are all comparable with similar recommendations in the earlier report, and will result in a welcome uniformity in the different branches of the profession. Throughout the report the need for refresher or "post-certificate" courses is emphasized, and suggestions are made for grants to enable nurses to attend such courses. Two criticisms are to be noted: (1) the committee does not consider that three months' experience in tuberculosis nursing is sufficient qualification for a tuberculosis visitor; (2) the committee has found that no statutory qualifications have been laid down for school nurses; it recommends that the appropriate Departments give attention to these matters. The new scales are to be retrospective from April 1 last, and the Ministry of Health, which is asking all employing authorities to put them into effect, is to make a grant of 50% of the additional cost (100% in the case of nurseries) provided the recommendations are adopted in their entirety. The Board of Education is following the same course for the school medical services.

#### RETRAINING OF DISABLED PERSONS

The increased attention so rightly given to rehabilitation of the injured person, culminating in the second reading in the House of Commons of the Disabled Persons (Employment) Bill, has called forth a reminder from the L.C.C. that rehabilitation has been part of the Council's medical services for the past thirteen years. It employs a large number of masseuses and physiotherapists and has established two special fracture centres, one north and one south of the Thames, where the latest advances in the treatment of fractures are put into practice. Occupational treatment, organized games, and physical exercises, together with special treatment for those in whom there are psychological hindrances to recovery, have been features at the Council's two convalescent homes—Queen Mary's, Sidcup, and Princess Mary's, Margate.

Many hundreds of disabled persons have been restored to whole or partial self-support at the L.C.C.'s training centres for patients

from its hospitals, while there are special arrangements whereby those suffering from neurosis and also the psychotic and higher-grade mental defective receive treatment and are helped to find suitable employment. Tuberculous patients who, though improved in health, cannot compete in the open labour market are accommodated at Papworth and Preston Hall, and for some years now the Council has subsidized the Spero workshops. As long ago as 1938 a survey was made of all those on long-term relief with medical certificates of unfitness due to neurosis. Most were found to be receiving adequate treatment, but as many as possible of the others were taken into occupation centres for gradual retraining. Good work has also been done among young and "improvable" vagrants; by the elimination of physical disabilities numbers have been retrieved from vagrancy. Then there is the education, including craft training, which is given to the physically defective in the Council's hospital and day schools. Thousands of young cripples have been successfully absorbed into industry since these schools were started 45 years ago. To-day hospital patients undergo a final hardening process before discharge. Those confined to bed for long periods are given regular exercises to keep up muscular tone, but as soon as they are up they go to physical training classes and to the workshops, where a great variety of work, from bookbinding to carpentry, is done. Occupation for the mind is provided in discussion groups and lectures. There are three L.C.C. hospitals where special provision is made for cases of war neurosis.

### MATERNITY AND CHILD WELFARE SERVICES OF LONDON

Large readjustments of maternity services in London are forecast in a report by the London Maternity Services (Voluntary Organizations) Joint Committee, which represents voluntary hospitals and district nursing associations undertaking midwifery within the Metropolitan Police district. There is now a shortage of maternity beds in the outer London area. The population of outer London—that is, London outside the L.C.C. area—is larger by some half a million than the population within the county, and yet, in a pre-war year, the number of maternity beds in that outer area was only half the number available in inner London.

The requirements of the metropolitan teaching hospitals have to be considered, however, before any general transference to the periphery is proposed. On the pre-war basis of 5,000 medical students taking their training at the London teaching hospitals, and of 700 taking their course in midwifery each year, with the requirement that each of them should deliver a minimum of 20 cases, 14,000 confinements, intern and extern, would be needed for their adequate training. In the committee's view, in post-war planning it would be unwise to allow for more than 1,500 to 2,000 district cases (extern). Moreover, it is probable that the number of undergraduates will increase in the immediate post-war years. Hence it is thought that at least 700 maternity beds, allowing for approximately 14,000 institutional confinements, should be reserved for the teaching of medical students.

The general conclusion of the committee is that in post-war planning additional midwifery accommodation should be provided towards the boundaries of the L.C.C. area and in outer London, and that the existing maternity beds in central London should be readjusted so as to ensure that adequate teaching provision is made for medical students. It is suggested that the Metropolitan Police district should be divided into areas, taking into account existing borough boundaries and the maternity facilities available, and arranging for each district to have a key hospital. The suburbs would be served by small maternity units working as annexes of the key hospitals. It is also urged that there should be close liaison between voluntary hospitals and local authorities on all questions relating to the future provision of midwifery accommodation and services so as to avoid wasteful overlapping and to ensure that beds are provided where they are most needed.

The key hospitals would be well-equipped maternity units with a minimum of 100 beds and accommodation for ante-natal and post-natal in-patients. A unit at or connected with a general hospital should have not fewer than 50 beds. Until these units can be provided small maternity homes and private nursing homes now in existence must continue to serve obstetric cases, and an endeavour should be made to arrange for close co-operation between them and the key hospital of their area. At present there are no large voluntary maternity units in

the north-west, south-west, or south-east of the County of London, but there were enough maternity beds in central London before the war, and if the teaching hospitals accept the recommendation of the Royal College of Obstetricians and Gynaecologists to provide their own maternity units, this will mean an addition of some 350 beds in this area. The committee therefore suggests that if as part of this plan the three lying-in hospitals in the centre of London—the City Maternity, East End Maternity, and the General Lying-in—could see their way to move towards the boundary of the L.C.C. area, and if the L.C.C. would agree to provide obstetric units in connexion with its hospitals in north-west, south-west, and south-east London, instead of on their present sites, the County of London would be surrounded by maternity hospitals which could, with some extension and improvement, serve as key hospitals for the outer London area.

### Proposed Unifying Board

After a review of the various components of the existing maternity and child welfare service, directed and controlled as they are by a number of different organizations, the committee proposes the setting up of a new authority to be appointed by the Ministry of Health and to bear some such name as the Maternity and Child Welfare Board for Greater London, with its appropriate place in the maternity section of a national health service. All the bodies concerned, including voluntary hospitals and consultants and general practitioners, as well as the local authorities, would be represented on the board, and a small executive should be set up with professional and technical panels, consisting of people with special qualifications as authorities on the subject and with experience of some branch of maternity or child welfare. This board would have power to make recommendations concerning the distribution of funds made available by the Government for this work in both voluntary and municipal institutions, and it would be responsible for all matters of policy affecting maternity and child welfare.

If the maternity service of London is to be really efficient, with no overlapping and no break in continuity in the care and supervision of the mother and her child, the arguments in favour of such a board, based on a partnership between voluntary organizations and local authorities, seem to be incontrovertible.

### MEDICAL RESEARCH IN EIRE

The Medical Research Council of Ireland (85, Merrion Square, Dublin) has made the following grants:

#### Whole-time Awards

Dr. Vincent C. Barry. Fellowship in organic chemistry to undertake an investigation into the chemotherapy of tuberculosis; work to be carried out in the Chemical Department of University College, Dublin, under the direction of Prof. T. J. Nolan and the Council's Chemotherapy Committee.

Dr. Michael Flynn. Fellowship to undertake an investigation into the typhoid carrier condition; the work to be carried out in the Department of Bacteriology, University College, Dublin, Grangegorman Mental Hospital, and the Dublin Fever Hospitals, under the direction of Prof. W. D. O'Kelly and in collaboration with the resident medical superintendents of the hospitals concerned.

Dr. Patrick A. McNally. Fellowship in bacteriology to undertake an investigation into the chemotherapy of tuberculosis; work to be carried out in the School of Pathology, Trinity College, Dublin, under the direction of Prof. R. A. Q. O'Meara and the Council's Chemotherapy Committee.

Dr. Diarmuid Murphy. Fellowship to undertake an investigation into the methods of production of penicillin, in the Botany Department, University College, Dublin, under the direction of Prof. J. Doyle, and in collaboration with Mr. Oliver Roberts.

#### Grants-in-Aid

Dr. Bryan Alton. For expenses in connexion with an investigation into the bacteriostatic effects of products of *Penicillium notatum* and other moulds, in the Department of Bacteriology, University College, Dublin, under the direction of Prof. W. D. O'Kelly.

Prof. T. W. T. Dillon. To enable him to employ technical assistance in his investigation of the problem of diuresis.

Prof. W. J. E. Jessop. For technical assistance for section-cutting in his research work.

Dr. A. G. G. Leonard. To enable him to maintain records of pollution by sulphur dioxide and suspended impurity at Merrion Street and at the Albert Farm, Glasnevin.

The following have had their grants renewed for further periods: Prof. R. A. Q. O'Meara, Mr. P. J. Boyle, Dr. O. FitzGerald, Mr. D. J. Hingerty, Dr. D. K. O'Donovan, and Miss E. O'Donovan.

## ROYAL COLLEGE OF SURGEONS

## THREE HONORARY FELLOWSHIPS

Major-Gen. W. H. Ogilvie has just returned to England after a visit to the United States and Canada, where he was authorized by the President and Council of the Royal College of Surgeons of England to present diplomas to the surgeons of these countries who had been awarded the Honorary Fellowship but who were unable to visit England at present.

On Oct. 30 Prof. Norman Strachan Shenstone of Toronto was admitted as an Honorary Fellow in the Governor-General's House in Ottawa. The Governor-General, the Earl of Athlone, himself an Honorary Fellow of the College, presided at the ceremony, and H.R.H. Princess Alice honoured the College by attending. A distinguished company was invited to Government House for the occasion.

On Nov. 8 Major-Gen. Ogilvie presented diplomas of Honorary Fellowship to two American surgeons, Prof. Robert Bayley Osgood and Prof. Everts Ambrose Graham. The ceremony took place in the British Embassy in Washington. His Excellency the Ambassador, Viscount Halifax, presided, and a distinguished company was invited to attend.

## Introductory Remarks by Major-Gen. Ogilvie

The Royal College of Surgeons of England stands in direct succession to a series of learned bodies who have striven, since the search for knowledge first began to replace the unquestioned acceptance of tradition, to further the science and art of Surgery. According to their lights, and within the limitations that the state of learning and material prosperity of their times imposed upon them, these guilds, societies, and corporations made it their concern to encourage the pursuit of learning, and to establish a high professional and ethical standard among their members and associates. Our College is proud of its stewardship during the years that it has been responsible for maintaining these traditions, and it has endeavoured to advance surgery in the related fields of research, of education, and of examination standards.

In research we have been helped by many generous benefactions, among which those of Bernhard Baron and Buckston Browne stand out in recent years. The Bernhard Baron laboratories occupying two floors of the College buildings in Lincoln's Inn Fields, and the Buckston Browne experimental farm in the grounds of Darwin's house in Kent, have given young surgeons a unique opportunity to follow John Hunter's famous advice, "Don't think: try the experiment." In education we have always been proud of having the best surgical museum in the world, and a library that is complete in its files of surgical books and periodicals. We have endowed lectures and demonstrations, single and in series, that provide a forum from which advances in surgery and allied sciences are made public. In examinations we are concerned with the standards of surgery and have two diplomas: the Membership of the College, which, with the Licence of the Royal College of Physicians, provides the most widely sought qualifying test in the United Kingdom; and the Fellowship, a hall-mark of surgical knowledge which is awarded after two examinations whose severity is proverbial.

The Fellowship of the Royal College of Surgeons stands high, partly because it marks the successful passage of this severe scholastic test, still more because the body of Fellows represent all that is best in the surgery of the British Commonwealth and Empire. Because any nation or society is the epitome of the qualities of its individual members, the College has always been proud to add to its ranks, as Honorary Fellows, leading surgeons of other members of the British Commonwealth of Nations and of the world. Honorary Fellowship is awarded to few. It is the highest honour the College can give, and the College has been honoured by those who have accepted it and whose names now stand on its roll. Because of the importance of the occasion, Honorary Fellows are required by custom to attend in the Council Chamber to receive their diplomas at the hands of the President, and to sign the roll of Fellows. As a Member of the Council it has been my privilege to attend several of these presentations. I felt, as many have done, the spell of a ceremony that has changed its detail and its place but has retained the tradition and very much the form of the days when Columbus first landed on these shores. The Council have decided to depart from custom and present the diploma over-seas, rather than wait for that indeterminate event, the cessation of hostilities, in order to present it in the home of the College. In making this decision, I know they have been influenced by the wish to give contemporary rather than belated recognition to the spirit of harmonious co-operation that has existed between the surgeons of our countries before, and still more during, the war, and to the scientific discoveries that the bodies which those who are with us to-day represent have contributed to the common cause.

As a senior member of the Council, I have been entrusted by the President, Sir Alfred Webb-Johnson, with the great privilege and honour of welcoming these eminent surgeons to the ranks of our Honorary Fellows.

Nov. 8, 1943: in the British Embassy at Washington

ROBERT BAYLEY OSGOOD.—Your name is a household word wherever orthopaedic surgeons are gathered together, and wherever the games of football and tennis are played throughout the world. You are a Harvard student. Throughout your life you have been associated with the Medical School of that renowned University, and by your reputation and your writings have helped to carry its name to every part of the world. Your work has been recognized in Europe by Honorary Membership of five orthopaedic societies, and by your appointment to the Hugh Owen Thomas Lectureship at Liverpool in 1925. In the first world war you served over-seas in 1917 and 1918, and in the latter year you were selected as consultant to the office of the Surgeon-General in Washington. To-day you stand in the enviable position of being recognized as one of the greatest orthopaedic surgeons in the world, and as one of the leaders of medical education, particularly of orthopaedic education, in the United States.

EVERTS AMBROSE GRAHAM.—I will not offend your modesty or strain my own memory by attempting to enumerate the many distinctions that go to make up your very remarkable record. I know that you have seven degrees; that six medals have been awarded to you; and that you have been appointed to nine different lectureships. You edit the *Archives of Surgery*, and that unique volume the *Year Book of Surgery*, to which every surgeon in every land turns for guidance. You are Professor of Surgery in Washington University and Surgeon-in-Chief of Barnes Hospital in St. Louis. You have been President of the American College of Surgeons, of the American Surgical Association, and of the Association for Thoracic Surgery, and you are now Chairman of the Committee in Surgery of the National Research Council in Washington. You have, among much fine work, made two outstanding contributions to surgery—the introduction of a method of contrast radiography in the biliary tract, and the demonstration that cancer of the lung can be cured by operation. You had the first successful case of pneumonectomy for malignant disease, and if, as I believe, that patient is alive to-day, you have by far the longest surviving cure. But your reputation among your colleagues, who have bestowed on you the highest honours in their gift, rests on a surer and more enduring foundation than that of technical contributions. Throughout your life you have striven for surgical education and the raising of surgical standards, and the high position which American Surgery now holds is in large measure due to your efforts in this respect.

Oct. 30, 1943: in the Governor-General's House at Ottawa

NORMAN STRACHAN SHENSTONE.—Your name had been familiar to me long before I had the good fortune to meet you six years ago, and indeed it is familiar to every surgeon in Britain. You had your school and university education in Toronto, and you have well repaid the teaching you received, for you in your turn have been a teacher in its medical school for thirty-five years, and your reputation, and the students you have sent out, have helped to carry the fame of its University to every corner of the world. In the first world war you served over-seas in 1916 and 1917, and returned to act as Consultant in the Department of Pensions and National Health in 1918, an office you have held ever since. Outside Toronto you are known chiefly for your contributions to thoracic surgery—it would be more accurate to say as one of the founders of that branch of surgery, for it was your technical contributions that first established the operation of lobectomy as a safe and justifiable procedure. In Toronto itself you are known as one who has always placed the welfare of others above his own, who has published little but has preferred to let his views pervade the surgical teaching of his university, and who has worked for his juniors rather than asking them to work for him. I know that they and your colleagues will rejoice at the honour conferred upon you.

For reasons of paper economy the 29th annual report of the Board of Control is not being printed or put on public sale during the war. At the end of 1942 the total number of persons suffering from mental disorder notified as under care in England and Wales was 147,596 (63,531 men and 84,065 women), of whom nearly 87% were being treated in institutions provided by local authorities. This was a decrease of 3,516 during the year, compared with a decrease of 4,048 during 1941. The average annual decrease for the five years ended Dec. 31, 1942, was 1,952. This contrasts with an average annual increase of 1,691 during the last five years of peace. Discussing the effect of war conditions on the incidence of mental disorders, the report states that the number of new admissions to public mental hospitals showed an increase of 340 on the previous year. This was due to a rise of 944 in voluntary admissions, less a reduction of 149 in temporary admissions and 455 in admissions under certificate.

## NEW YEAR HONOURS

The names of the following members of the medical profession were included in a New Year Honours List published in the *London Gazette* on Jan. 1:

*Knighthood*

Prof. FRANCIS RICHARD FRASER, M.D., F.R.C.P. Director-General, Emergency Medical Service.  
WALTER HAWARD, O.B.E., M.B., B.S. Director-General of Medical Services, Ministry of Pensions.  
Col. GEORGE WYKEHAM HERON, C.M.G., C.B.E., D.S.O., M.R.C.S., L.R.C.P. Colonial Medical Service, Director of Medical Services, Palestine.  
THOMAS JONES, M.R.C.S., L.R.C.P., J.P. Chairman of the Anglesey Education Committee.

*C.B. (Military Division)*

Major-Gen. ALEXANDER GORDON BIGGAM, O.B.E., M.D., F.R.C.P., late R.A.M.C., Honorary Physician to the King.  
CHARLES MAX PAGE, D.S.O., M.S., F.R.C.S. Lieut.-Col. (Acting Major-Gen.), R.A.M.C.  
CHARLES PUTNAM SYMONDS, M.D., F.R.C.P. Acting Air Commodore, R.A.F.V.R.

*C.I.E.*

Col. THOMAS CRAWFORD BOYD, F.R.C.S.I., I.M.S. Inspector-General of Civil Hospitals, United Provinces.  
Lieut.-Col. AUGUSTINE SARGOOD FRY, F.R.C.S.Ed., I.M.S. Professor of Operative Surgery, King Edward Medical College, Lahore.  
Lieut.-Col. ARTHUR DENHAM WHITE, F.R.C.S., I.M.S. (ret.).

*C.V.O.*

FRANCIS HUGO TEALE, M.D., F.R.C.P.

*C.B.E. (Military Division)*

BASIL CEDRIC ASHTON, M.B., Ch.B. Col. (Temp. Brig.), I.M.S. Honorary Surgeon to the King.  
LANCLOT MILLER CORBET, M.B., B.S. Acting Group Capt., R.A.F.O.  
FREDERICK HARRIS, M.C., M.B. Lieut.-Col. (Temp. Col.), R.A.M.C.  
HENRY BRICE PARKER, D.S.C., M.B., B.S. Surg. Capt., R.N. (ret.).

*C.B.E. (Civil Division)*

CHARLES HERBERT BEST, M.D., D.Sc., F.R.S., F.R.C.S. Co-discoverer of insulin with the late Sir Frederick Banting of Toronto.  
WILLIAM LESLIE BURGESS, M.D., F.R.C.P.Ed., D.P.H. Medical Officer of Health, Dundee.  
GEORGE LISSANT COX, M.D. Chief Tuberculosis Officer, Lancashire County Council.  
ALAN NIGEL DRURY, M.D., F.R.S. Lately Member of the Scientific Staff, Medical Research Council.  
DUNCAN ARCHIBALD LAMONT GRAHAM, M.B., F.R.C.P. Dean, Department of Medicine, University of Toronto; former President, Royal College of Physicians and Surgeons of Canada.  
Prof. SYONEY ALFRED SMITH, M.D., F.R.C.P.Ed. Chairman of the Scottish Central Medical War Committee. For services to Civil Defence.  
CLAUDE EDWARD TANGYE, M.D., D.P.H. County Medical Officer of Health, Wiltshire. For services to Civil Defence.  
MAURICE LAWRENCE TRESTON, F.R.C.S., F.R.C.O.G. Col., I.M.S. Inspector-General of Civil Hospitals, Burma.

*O.B.E. (Military Division)*

GUY PASCOE CROWDEN, T.D., M.R.C.P. Lieut.-Col., R.A.M.C. T.A.  
CECIL WOOD FLEMING, D.M., M.Ch., F.R.C.S. Wing Cmdr. (now Acting Group Capt.), R.A.F.V.R.  
ROBERT WILLIAM HIGGINS, M.B., B.Ch. Surg. Cmdr., R.N.  
JOHN EDWARD GEORGE MCGIBBON, M.B., B.S. Squad. Ldr., A.A.F.  
EOGAR ALEXANDER PASK, Acting Squad. Ldr., R.A.F.V.R.  
JAMES MACLURE SMELLIE, M.D., F.R.C.P., Lieut.-Col., R.A.M.C., T.A.  
PAUL ALFRED TURNER SNEATH, Lieut.-Col., R.C.A.M.C.

*O.B.E. (Civil Division)*

PETER PAUL DEBONO, M.D., F.R.C.S. Professor of Surgery, Malta University.  
JOSEPH RICHARD GREGORY, M.D. Director, Kenya Branch, British Red Cross Society.  
CHARLES MERRILL SCHAFETER, M.B., F.R.C.S.Ed. Surgeon working in Church Missionary Hospitals in Persia.  
HAROLD EDWARD SKEETE, M.D., C.M. For public services in Barbados.

LEONARD ANTHONY PAUL SLINGER, M.B., B.Ch. Colonial Medical Service, Resident Surgeon, Victoria Hospital, St. Lucia.  
MARGARET WILKIE, LADY BHOORE, M.B.E., M.B., Ch.B. Central India.

*M.B.E. (Military Division)*

CLARENCE MELVILLE BETHUNE, Major, R.C.A.M.C.  
JOHN WEIGHTMAN BRIDGE, Major, R.C.A.M.C.  
RICHARD JAMES CAIRNS, M.B., Ch.B. Capt., R.A.M.C.  
ALFRED LEONARD CRADDOCK, M.B., B.S. Capt. (Temp. Major), Burma Army.  
ERIC RUDOLPH HILL, Lieut. (Acting Capt.), I.A.M.C.  
THOMAS MILLER, V.D. Major, R.C.A.M.C.  
FRANCIS LESLIE POTTER, Capt., R.A.M.C.  
CHARLES MARTIN ROW, Capt. (Temp. Major), R.A.M.C.

*M.B.E. (Civil Division)*

RATNAKAR NARAYAN BHAINDEKAR, M.B., B.S. Divisional Warden, A.R.P., Dadar West Division, Bombay.  
DAVID JAMES MASTERTON MACKENZIE, M.B., Ch.B. Acting Principal Medical Officer, Bechuanaland Protectorate.  
MOHAMED ALI RANA, M.R.C.S., L.R.C.P. For public services in Kenya.

*Kaisar-i-Hind Gold Medal*

BASIL FRANKLIN EMINSON, M.B., B.S. Lieut.-Col., I.M.S. (ret.). Civil Surgeon, Karachi, Sind.  
REGINALD ARTHUR HAYTHORNTHWAITHE, B.M., B.Ch. Major, I.M.S., Civil Surgeon, Khasi and Jaintia Hills, Assam.  
JOHN LOWE, M.D. Co-ordinator of Research, School of Tropical Medicine, Calcutta.  
JEAN MURRAY ORKNEY, M.B., Ch.B., D.P.H. Women's Medical Service, Director, Maternity and Child Welfare Bureau, Indian Red Cross Society.

Our readers will also learn with gratification of the knighthood to be conferred on Capt. G. S. Elliston, M.P., son of a former President of the B.M.A. and brother of the late Guy Elliston Financial Secretary and Business Manager of the Association; and on Prof. J. C. Drummond, D.Sc., scientific adviser to the Ministry of Food.

## Medico-Legal

## DOCTOR ACQUITTED OF RAPE

At his second trial, which lasted four days and ended on Dec. 16, Dr. Krishna Morishwar Pardhy, F.R.C.S., a Brahmin aged 68, was acquitted of the rape of Mrs. Lucy May Pearson. At his first trial in July the jury failed to agree. According to the newspaper report<sup>1</sup> Mr. and Mrs. Pearson had known him for some years and had recommended relatives to him: he practised at Elvetham Road, Edgbaston, Birmingham, as a gynaecological surgeon. The case for the prosecution was that he was examining Mrs. Pearson in his consulting-room, and that her husband was waiting in the same room behind a screen. The report leaves so many gaps that it is difficult to form a picture of what the couple really alleged in evidence, but apparently their evidence was to the effect that the doctor made sexual connexion with Mrs. Pearson without her becoming aware of it for some little time; when she realized what he was doing she called to her husband, who came out, caught the doctor by the wrists, and called him a swine. The doctor at once stoutly denied misconduct, and in his evidence said he had practised in Birmingham for 35 years, had suffered from prostatitis for 12 years, and at the time of the incident was tired after performing six operations. As the couple were leaving the house, he said, Mr. Pearson drew some money from his pocket, jingled it, and said, "Mr. Pardhy, you are not a psychologist." Mrs. Pearson was described by her own doctor as a placid, sensible woman. After an absence of 45 minutes the jury found Dr. Pardhy not guilty. Medical men are always being advised not to examine a woman without the presence of a third person. This case shows that for safety the third person must be an assistant of the doctor.

<sup>1</sup> *Birmingham Post*, Dec. 15, 16, and 17, 1943.

O. C. Lord and M. J. Stewart (*J. Laryng. Otol.*, 1943, 58, 263) who record a personal case, state that osteoclastoma of the temporal bone is a very rare disease, only two previous well-authenticated cases having been described. Their patient was a woman, aged 50, in whom the clinical duration of the disease was just over three years. The histological diagnosis was made two years before death by examination of a recurrent nasal polypus. Treatment by partial excision and radiation gave good results for a time. At necropsy the tumour was found to have extended to the base of the skull and had invaded the cerebellum.

## Correspondence

### Sciatica

SIR.—Sir Arthur Hurst's provocative essay on the treatment of sciatica (Dec. 18, p. 773) is both timely and chastening. I would suggest, however, that he has done scant justice to the part played by orthopaedic surgeons in the attempt to place the sciatica problem on a rational basis. It is many years since orthopaedic surgeons began to insist that sciatica is a symptom and not a disease; that true sciatic neuritis is rare; that sciatic pain is often referred pain (e.g., in osteo-arthritis of the hip); and that the causal lesion in a large group of cases is to be discovered in that complex system of articulations embraced by the lumbar spine and sacro-iliac joints. In common with physicians and neurologists, orthopaedic surgeons have also long been aware that many patients with backache and sciatica are the victims of a formidable psychological disturbance.

From the special standpoint of the orthopaedic surgeon the conventional diagnoses of lumbago and sciatic neuritis were first challenged nearly forty years ago by the Boston Orthopaedic School (Goldthwait and Osgood<sup>1</sup>). From this emerged the concept of sacro-iliac "strain" and lumbo-sacral "strain" as clinical and pathological entities to be treated by rest, fixation, forced mobilization, or in the last resort by operative fusion, in accordance with the special circumstances of the individual case, and not in accordance with the tenets of rival schools of orthopaedic practice. As time went on there were many successes, but far too many failures. In consequence orthopaedic surgeons began to look for a more satisfying explanation of the backache-sciatica symptom complex. During this period attention was directed to two contributory aetiological factors—abnormal posture and anatomical variations at the lumbo-sacral junction. We now attach little significance to the role of such anatomical variations as unilateral sacralization, but abnormal posture is a factor to be reckoned with in any re-educational programme for the treatment of backache and sciatica.

The next phase witnessed the intervention of the Italian school of orthopaedics when Vittorio Putti (1927) of Bologna, developing the notion of Sicard, first put forward the view<sup>2</sup> that sciatic pain—and more especially that striking clinical picture, sciatic scoliosis—was a symptom of arthritis of the interarticular joints of the lumbar spine. For the treatment of this condition Putti used the conservative measures of heat, rest, and fixation in plaster, but in intractable cases practised the operation of removal of the diseased articular facets—a procedure designed to decompress the irritated nerve roots lying in the intervertebral foramina. Sir Arthur Hurst has apparently overlooked the fact that the "vertebral arthritis theory" is thus at least sixteen years old, and that Mr. Blundell Bankart, who at the present time is almost alone in his unqualified support of this theory, has never claimed it as his own creation. Like sacro-iliac and lumbo-sacral strain, vertebral arthritis as a common cause of sciatica has in turn had its day. No one would deny the existence of these particular lesions, but we are compelled to believe that they form a minority group.

And now at long last a more concrete lesion of the lumbar spine has come to light—the disk protrusion. This lesion is a manifestation of a disturbance of the mechanics of the lumbar spine comparable in some respects to internal derangement of the knee-joint, and thus generically an "orthopaedic" lesion which may not necessarily require operative treatment, as pointed out by C. P. Symonds.<sup>3</sup>

In the comparatively short space of time which has elapsed since the pioneer joint contribution of Mixter, a neurological surgeon, and Barr, an orthopaedic surgeon, neurosurgeons in America and Great Britain have already reaped a rich harvest of cures by removal of the projecting disk fragment in cases selected from the large numbers of sciatica patients who continue to find their way to orthopaedic surgeons. In the majority of orthopaedic clinics to-day patients with backache and sciatica

are carefully studied by surgeons fully aware of the manifold causes of these symptoms. Heaven is thus often exceedingly helpful to the victims of sciatica, despite Sir Arthur Hurst's quotation from an unknown writer which prefaces his essay! I am accustomed to teach my students that the sciatica patient falls into one of five main clinical groups, and that each group should be considered in turn in the process of elimination which leads to diagnosis: (1) pelvic visceral disease; (2) bony lesions of the lumbar spine, pelvis, and femora—i.e., lesions essentially destructive in type (inflammatory or new growth); (3) joint lesions of the spine, pelvis, and hips (in this group the prolapsed disk has displaced the sacro-iliac strain and vertebral arthritis as the pivotal lesion); (4) central nervous lesions—e.g., cauda equina tumours; (5) pseudo-sciatica—fibrositis of the fascial, ligamentous, and muscle masses in the lumbar region, buttocks, and thighs.

In the *Army Medical Department Bulletin*<sup>4</sup> the fibrositic group is regarded as numerically important. This at the present time seems to be the outstanding controversial issue in the problem of the causation of sciatica.—I am, etc.,

Manchester.

HARRY PLATT.

SIR.—I was particularly interested in Sir Arthur Hurst's essay on sciatica, because my own comparatively limited experience of the complaint had led me to a somewhat similar view. Some time ago I had to deal with about half a dozen more or less intractable cases of sciatica all of which had experienced some unusually severe emotional strain shortly before the onset of pain. Typical of these was a university professor who, coincident with his retirement, lost a dearly loved wife. Then, while convalescing in a nursing-home, he had contracted sciatica just as he was beginning to feel he could face life without its old associations. I regret to say that at the time he told me his story my knowledge of sciatica had not been "debunked," so that I missed the obvious clue to its cause and submitted him to one useless "orthodoxy" after another. However, the coincidence of these cases served to draw my attention not only to the possibility of a psychic origin but also to the probable way this produced the common effect.

There seemed to be no reason to quarrel with accepted causes of sciatica, which might well be present in many people with or without the complaint. Certainly one would not omit thorough external and rectal search for these. But whatever such examinations might disclose it appeared that the actual onset of pain was more likely to be determined by some factor that increased the patient's perception of it than by any real event of a purely organic variety. In my cases I was accordingly led to suppose that pain arose when there existed an urgent need for escape from some unbearable memory under circumstances that provided insufficient distraction of a less morbid kind. (Presumably this incompatible "memory" need not be of recent origin or as well known to either patient or doctor as it happened to be in my cases.) Then as soon as consciousness is fully focused upon the sciatic pain it is in turn greatly intensified by all the muscular and postural adjustments by which the body vainly endeavours to seek relief. Such an aetiology and sequence of events is well recognized in relation to pains in all parts of the body, but, as Sir Arthur Hurst points out, sciatica must frequently belong to this category, judging by the variety of causes and treatments assigned to it.

I would like to extend Sir Arthur Hurst's observations on treatment a little further than his recommendation for some form of suggestion. The premises on which this is based seem to call for attempts to eradicate the malady as well as the pain by defining its nature and cause to the patient. For instance, one of the cases to which I have referred was a man of about 50 who had done little or no work since the last war due to injuries sustained and the fact that it had left him a nervous wreck. This man suffered severely for nearly a year from sciatica that would not yield to tablets, medicine, injections, physiotherapy, or anything else. The masseuse obtained a little relief for a time mainly by postural correction and relaxation of dorsal muscular spasm, but really nothing seemed to be much use however confidently it was presented to the patient. Now shortly before the onset of the pain the patient's father had died in an infirmary, and I found that he was

<sup>1</sup> *Boston med. surg. J.*, 1908, No. 21-22.  
<sup>2</sup> *Lancet*, July 9, 1927. (Ad. Lomboartrite e sciatica vertebrale, Bologna, 1936.)  
<sup>3</sup> *Sciatica*, Medical Annual, 1943.

<sup>4</sup> *Army Medical Department Bulletin*, No. 16 (Oct. 1942).

haunted by a conviction that he had been instrumental in his father's death. A complete explosion of this fallacy, together with detailed explanation of how he had been seeking refuge in pain, was followed by its disappearance in the course of a couple of weeks.

However, quite apart from one's own personal experience, it seems to me that if one accepts Sir Arthur Hurst's very convincing arguments in favour of a functional interpretation of sciatic pain it is no less incumbent on one to find and eradicate the cause than if one believed this to be of an organic nature. If simple suggestions of cure succeed in overcoming the pain one can hardly feel confident that one has done any more than suppress a symptom, however gratifying that may be. In dealing with pain arising from a possibly progressive organic disease such complacency would generally be regarded as quite unscrupulous. In that case attempts of any sort solely directed towards relief of pain would be regarded as nothing short of quackery unless the case had been proved to be hopeless. Yet if in the absence of organic disease a case yields to suggestion one seems to be exonerated from knowing or doing anything more about it until the almost inevitable recurrence of identical or other symptoms of the disorder.—I am, etc.,

Eye, Suffolk.

J. SHACKLETON BAILEY.

SIR,—Discussion on the treatment of a symptom common to many disorders is seldom illuminating. There would be no more difficulty in making fun of the treatment of headache than Sir Arthur Hurst finds in ridiculing the treatment of sciatica. The relief of headache may demand operations, drugs, rest, exercises, or psychotherapy; no one would discern anything unreasonable in that.

Nowadays sciatica is largely employed as a synonym for pain felt to radiate down the back of the lower limb from above. A medical definition consonant with this usage would be "pain common to various deep-seated lesions placed at the proximal extent of the fourth lumbar to second sacral segments." The alternative nomenclature is to regard sciatica as a diagnosis and confine its use to cases showing signs of diminished conduction along the sciatic nerve. This usage cannot be recommended, since it results in several inconsistencies—namely, that in about half of all cases of sciatic periradicularitis no signs of a parenchymatous lesion ever appear; that two entirely distinct conditions (sciatic neuritis and sciatic periradicularitis) go by the same name; that cases of pure backache caused by sciatic periradicularitis have to be called sciatica. The nomenclature that commends itself to me is: (a) sciatica—the name of a pain; (b) sciatic periradicularitis (which should be divided into frictional and non-frictional)—affections primarily of the sheath of the sciatic nerve-roots; (c) sciatic neuritis—primary affections of the parenchyma of the sciatic nerve.

The rational treatment of sciatica is that of the causative lesion. It differs in no way whether merely local or much referred pain is present. A list of the commoner lesions setting up unilateral sciatica and their appropriate treatment follows:

*Deep lumbar fasciitis*: deep massage; if this fails, division of the affected part of the fascia.

*Gluteal myositis*: deep massage.

*Gluteal fasciitis*: deep massage.

*Sacro-iliac strain*: corsetry, preceded if necessary by manipulative reposition of the joint.

*Sacro-iliac arthritis*: local deep x-ray therapy.

*Non-frictional sciatic periradicularitis*: epidural local anaesthesia.

*Frictional sciatic periradicularitis*: manipulative reduction of the displaced fragment of intervertebral disk; if this fails, immobilization; if this fails and the symptoms warrant, operative removal of the protruded disk.

*Intermittent compression of the fifth lumbar nerve-root*: rest; if this fails, consideration of Bankart's decompression of the root by removal of the lateral articulation.

*Sciatic neuritis*: removal of the cause when it can be found—e.g., poisoning with a heavy metal or alcohols. Many cannot be eliminated—e.g., secondary deposits.

*Functional pain*: psychotherapy.

There are many pains which give rise to very little by way of physical signs; sciatica is one of them. None the less, the pain of sciatica is very real. The examination of the patient is difficult and tedious. It must disclose whether he is suffering from (a) a nervous lesion and, if so, which sort; (b) a muscular,

fascial, or ligamentous lesion, and, if so, exactly where; (c) nothing organic. Only on the basis of an accurate diagnosis can effective treatment be offered for this common symptom.—I am, etc.,

London, W.1.

JAMES CYRIAX.

### Operation for Prolapsed Intervertebral Disk

SIR,—I am quoted by Sir Arthur Hurst in your issue of Dec. 18 as convinced that in Service patients the operation for prolapsed intervertebral disk has proved unsuccessful in getting men back to duty. This was the opinion which I expressed in a discussion at the Royal Society of Medicine two years ago. Since that time, as the result, I believe, of better selection of cases, improved surgical technique, and a more carefully planned convalescence, the results of operation have been much better than they were during the period from which my earlier experience was drawn. It is to be hoped that surgeons who have followed up their cases will soon be able to give us details of the percentage of patients able to return to, and remain at, full duty after operation. We need also a follow-up of a comparable series treated by immobilization before we can improve our judgment as to the circumstances in which operation is desirable. In certain cases I believe it offers the best chance of return to duty.—I am, etc.,

Oxford.

C. P. SYMONDS.

### Tuberculosis in Belgium.

SIR,—In your issue of Dec. 18 (p. 800) you give an account of the question put by Mr. Oldfield to Mr. Dingle Foot in the House of Commons on Dec. 7 with regard to the increase in the number of registered cases of tuberculosis in Belgium. The number has risen from 69,079 in Dec., 1941, to 109,511 in Feb., 1943—that is to say, from 8.3 per 1,000 of the population to 13.3. While accepting the latter figure, Mr. Foot remarked that slight cases were included, because "anyone might apply to his doctor for a certificate showing that he was suffering from tuberculosis."

According to the evidence which has reached me from Belgium since 1942, and which has recently been confirmed by Belgian doctors who have succeeded in escaping from Belgium, the registration which entitles a patient to a supplementary ration is extremely difficult to obtain and is not granted merely on the production of a doctor's certificate. Either an x-ray photograph showing internal lesions must be added or conclusive sputum specimens. In a case of tuberculosis of the eye the doctor was unable to obtain a supplementary ration card for his patient because neither a photograph nor the sputum would be evidence.

The estimate of one-third of the children under 18 suffering from tuberculosis and other diseases is quoted in a report issued in May, 1943, by the American Board of Economic Warfare. It is based on information emanating from Sweden. It is not the first time that Swedish and Swiss observers have confirmed reports received by the Belgian Red Cross in London.—I am, etc.,

Radlett.

EM. CAMMAERTS.

### Treatment of Obstetric Shock

SIR,—I was most interested in Dr. I. S. Fox's contribution (Dec. 18, p. 781) on the value of immediate blood transfusion in primary obstetric shock.

He describes in detail a case following a short normal uncomplicated delivery, which responded very satisfactorily. If I may be allowed one point of criticism, however—expression of placenta by Credé's or any other method should not be attempted so quickly after delivery. Another point—I doubt whether the condition is as rare as he suggests, as I have had two similar cases in a short series of approximately 300 deliveries.

Both patients were primiparae with normal histories and pregnancies, who delivered spontaneously after short and easy labours, one in fact being B.B.A. Shortly after delivery, with normal blood loss and before any attempt was made to express the placenta, both cases collapsed with obvious and severe obstetric shock. The usual domestic antishock measures were instituted immediately without much response, except that in

one case intracardiac adrenaline was successful in restoring cardiac rhythm. Pituitary had not been used in either case. An urgent summons for the local "flying squad" was answered quickly, and transfusion of whole blood was most successful.

I agree whole-heartedly with Dr. Fox as to the value of the "flying squad" in these and similar cases, and would urge that each large centre of population should have the benefit of this service, as such cases are not fit for removal to hospital.—I am, etc.,

Newcastle-upon-Tyne

IRVING STOLL.

### Immediate Blood Transfusion in Obstetric Shock

SIR,—I was very interested in the article by Dr. I. S. Fox under the above title (Dec. 18, p. 781). Several similar cases have occurred in this hospital where there was severe shock with a blood pressure of 70, 50 mm. Hg in association with little blood loss and a retained placenta. Immediate transfusion with plasma and whole blood in one case completely failed to relieve the condition. It was then decided to remove the placenta manually under gas-and-oxygen anaesthesia, and within 10 minutes of the removal the pulse had improved greatly and within 20 minutes the blood pressure had risen to 110/60 mm. Hg. In all cases of obstetric shock in the presence of a retained placenta with little blood loss prompt manual removal of the placenta has improved the condition immediately without a transfusion.

The exciting cause of the shock appears to be a histamine release from the partially separated placenta and absorption into the maternal circulation, and removal of the placenta cures the condition. In the reported case, shock might also have been due to injudicious use of Credé's method, which in itself is capable of producing shock. The rationale of whole-blood transfusion is difficult to understand, and plasma or serum in any case ought to be sufficient to combat shock in the absence of bleeding. It appears to be rather a waste of whole blood, which should be reserved for cases requiring haemoglobin because of severe anaemia either present before delivery or due to bleeding.—I am, etc.,

Norfolk and Norwich Hospital.

W. P. HIRSCH.

SIR,—I read with interest the article by Dr. I. S. Fox on immediate blood transfusion in obstetric shock as I had an almost identical experience earlier in the week.

Mrs. X., 2 para aged 32, started in labour about 10 p.m. on Dec. 13, 1943. I was sent for at 1 a.m. on the 14th and delivered her of a baby weighing 9½ lb. at 2.10 a.m. She had terminal chloroform anaesthesia when the head was on the perineum, and the labour otherwise was quite natural, no instruments being used. There was no laceration of the perineum, and bleeding was minimal. At 2.30 a.m. I attempted gently to express the placenta by Credé's method, but was unsuccessful, so desisted and sat down to wait. Five minutes later the patient fainted. There was no further bleeding and the uterus was quite firm. The foot of the bed was raised, hot-water bottles applied, coramine injected. She came round, but kept threatening to faint. At about 3 a.m. I expressed the placenta, and the patient said she felt all right. There was very little further bleeding. I gave her 0.5 c.cm. of vituritrin at 3.15 a.m., and as she seemed quite settled with a pulse of good volume and about 80 per minute I left her about 20 minutes later. However, within half an hour I was recalled by phone as the nurse said she had "gone off" again.

On my return the nurse was already giving rectal saline, but her pulse was very faint, the patient's colour greyish, and the pupils widely dilated. I called out the local "flying squad," but when it arrived the patient's condition was better, though she still tended to faint. The obstetric specialist decided, as it was obstetric shock and not due to haemorrhage, to give a pint of plasma, and after two or three complaints by the patient of feeling sick and faint during its administration the pulse improved and she felt much better, and she had no further trouble.

I also was at a loss to ascribe a cause for the condition, and it was my first experience of it in 20 years' practice. Her uterine contractions had been good, it was a gentle labour, and there was little loss of blood. I thought it had something

to do with the retention of the placenta, but I also felt that there was some psychological factor, as her husband was away in the R.A.F., her other child, aged 2 years, was ill with a cold, she was alone in the house with this sick child for 2 days (the day before and the day—the 12th—on which the confinement was expected), and her neighbours on each side of her house were all suffering from influenza, so that she had been very anxious as to how she was to get in touch with the municipal midwife. Fortunately, on the 13th her step-mother, who was to have looked after her, was sufficiently recovered to come.—I am, etc.,

A. BARLOW.

### Detection of Death under Anaesthesia

SIR,—In Mr. Harold Dodd's article on blood-pressure readings in general surgery (Dec. 25, p. 811) I note that he conforms to modern surgical procedure by having blood-pressure readings taken before, during, and after operations, as has been done at most good hospitals, I believe, for many years, and certainly at my own. I am a little disturbed, however, to read of his experiences when operations are done without blood-pressure observations, for he records that on three occasions death on the table was first detected by the surgeon. I recommend, with considerable confidence, the rule that a surgeon should only employ an anaesthetist who is at least as nimble as he is at detecting the onset of an acute attack or "mors" without the aid of a blood-pressure cuff.—I am, etc.,

London, W.1

JOHN HOSFORD.

### Heroin during Labour

SIR,—I was interested to read in your issue of Dec. 18 (p. 795) that Dr. W. Edwards had found trilene so efficient in producing analgesia in obstetrics. It has to be borne in mind, however, that, since trilene has only recently been introduced as an anaesthetic agent, our knowledge of its toxic effects may not yet be complete. Three cases of permanent trigeminal paralysis following the use of trilene were described only last month in the *Journal* (Dec. 4, p. 713).

During the past five months every case admitted to this hospital has been given heroin during labour, and I have come to the conclusion that this is the most generally useful drug in normal labour. When the cervix is 2 to 3 fingers dilated 1/6 gr. heroin is injected, and this is followed by 1/12 gr. heroin when the cervix is almost fully dilated and only the anterior lip remains to be taken up. This is the minimum amount which is given. In a long first stage additional doses of 1/12 gr. heroin are given. If it is found that the cervix is almost fully dilated or that the second stage has begun when the case is admitted, 1/6 gr. heroin is given straight away, no account being taken of when delivery is expected to take place.

With this technique, which has been employed now in over 200 cases, the pains of both the first and second stages are adequately relieved, and in the vast majority of cases no supplementary anaesthetic is required at all. After the first dose of heroin the patient either sleeps for a while or enters into a pleasant doze. The importance of relaxation, as expounded by Dr. Grantly Dick Read, is not overlooked, and every patient is taught and encouraged to lie relaxed and still during the first-stage uterine contractions. Bearing-down efforts in the second stage are not impeded in the slightest. The mother does not cry out pitifully for relief when the head is on the perineum. There is no moaning, no groaning. The child cries spontaneously when it is born. I have on many occasions given 1/6 gr. heroin to women admitted in the second stage of labour. Delivery has taken place at all times from ten minutes to two hours later, and in not one of these cases did the child fail to cry lustily and spontaneously.

Not only is the normal course of labour not interfered with, but the method is pleasant, as heroin produces a euphoria unrivalled by any other narcotic drug, and the disagreeable features of inhalation anaesthesia are avoided. Patients can be left alone after being given heroin, a factor which makes the method ideal for domiciliary midwifery. In my opinion the heroin technique, as outlined above, could be safely entrusted to midwives.—I am, etc.,

### Industrial Lead Poisoning

SIR,—I was most interested and gratified by Dr. Lane's letter (Dec. 11, p. 760). I had been rather shaken by the comments in the leading article on industrial plumbism referred to by Dr. Lane, inasmuch as I have proved to my own satisfaction the value of regular and periodic punctate basophilic counts in the lead works with which I have been associated as appointed surgeon for the past two years. Ninety-five per cent. of the employees—of whom there are about 600—submit willingly to the taking of their blood, and each man working where the hazard is known to be particularly great has his blood examined every 3 to 4 weeks. The result of the count determines the advisability or otherwise of the transference of the man to a part of the works where the risk is less. Again, blood counts for punctate basophilia are of the utmost value to the management, for if it is discovered that a batch of workmen on one particular process suddenly develop a markedly raised count the conclusion is obvious—the ventilation at that process is at fault, and this must be rectified.

I maintain that with the co-operation of the management the lead-works doctor is in a position to reduce industrial plumbism in such works to a minimum. I might add that in the works alluded to in this letter there has not been a single case of plumbism in 18 months. The blood cells are counted with the aid of dark-ground illumination; the granules are so much easier to define than when the direct method is used, and consequently much time and eyestrain are saved.—I am, etc.,

Newcastle-upon-Tyne.

H. C. WRIGHT.

### Shock Treatment of Mental Disorder

SIR,—Having been privileged to be a co-introducer of electrical convulsion treatment to this country in 1939, it happens also that I am a practising psychotherapist upon limited but intensive Freudian analytical lines; I therefore claim a measure of impartiality in venturing to reply to Dr. Winnicott's observations upon this twofold topic (Dec. 25, p. 829).

I fear there is a basis of truth, which should not, however, be exaggerated, in your correspondent's contention that the even course of medical evolution has been interrupted and set back by the widespread application of convulsion therapy. Should this be the case it is a regrettable, though perhaps to some extent inevitable, sequence of events largely owing to the inherent difficulties associated with psycho-analytical practice, particularly where time and money are concerned. Among psychiatrists generally there has been and still exists a failure to grasp and appreciate the great importance and fundamental significance of that arduous and prolonged psycho-analytical approach, confronted as it is by the imperative necessity of the analyst himself undergoing analysis. To me it becomes increasingly clear that convulsion therapy, when indeed not self-sufficient, should be regarded as an adjuvant means of promoting accessibility to later psycho-analytical investigation and treatment.

Regarding the alleged harmfulness of convulsion therapy—a view nowadays quite unusual—I would say that over four years of clinical experience, including the completion of over 8,000 major inductions with only two minor fractures and no untoward sequelae, has convinced me of its very wide margin of safety. To protest against convulsion therapy upon ethical grounds in the face of such findings, and when such treatment *per se* so commonly results in speedy and sometimes lasting improvement, suggests an emotional bias on the part of your correspondent, whose main thesis I am, nevertheless, ready to support. Because it is founded upon strict laws of evidence, sooner or later the essential soundness of psycho-analysis will surely prevail, both against inherent difficulties and also the vast wall of ignorance and prejudice which hinders its acceptance. Practicability and ease of administration, together with the likely promise of speedy results, have ensured the success of convulsion therapy; but psycho-analysis is much more than a therapy: it is nothing less than a science in the making. Its methods, necessarily slow and laborious, are unspectacular, but they offer in return knowledge and understanding of the mind, also therapeutic possibilities where all else fails.

It is indeed unfortunate from the standpoint of science that the value of the analytical approach and convulsion therapy

varies inversely with their practicability. In the ready practicability of convulsion therapy lies its immediate advantage, but also a certain kind of danger; this latter, however, is not a physical danger to the subject but one of therapeutic superficiality by the operator, who is tempted to be satisfied with perhaps mere palliation and to disregard that proper investigation and furtherance of understanding which alone are worthy of the name of science.

In questions of therapy, however, there is a need to be practical as well as idealistic, and to remember that the one essential characteristic of a successful therapy is its power to ameliorate the condition of the patient. There is no room for exclusiveness where multiform successful treatments are concerned; the determining factor in the choice of any particular treatment will always lie in the practicability of its application. It behoves us nevertheless to place first things first, and to maintain a proper perspective and a sense of relative values. As regards these two approaches to treatment, there surely can be no room for doubt as to their greatly differing significance and value to the scientist. The priority of importance of the psycho-analytical approach, save as a clinical method of ready and widespread applicability, is altogether overwhelming.—I am, etc.,

Warrington Park Hospital.

WM. H. SHEPLEY.

SIR,—I have read with amazement Dr. Winnicott's remarkable letter dealing with the above subject. Although the *modus operandi* of this form of treatment is still in doubt there is surely no excuse for describing it as "a mediaeval attempt to drive out evil spirits." The author is apparently under the impression that fear is the operative factor. In the cardiazol method of inducing convulsions there was a reasonable doubt as to the part played by fear, but in electrically induced convulsions fear does not or should not exist. If the patient is afraid, it is because of some ill-advised description of the treatment, such as appeared in the lay press and was most justifiably criticized by Dr. T. M. Cuthbert. There is surely no question of "inflicting pain" on the patient, considering the fact that most patients after an induced convulsion will firmly maintain that they have received no treatment and will confabulate in a remarkable manner in order to explain away their period of amnesia. The following description of the treatment by an intelligent patient is typical. In several letters to friends he stated: "This new electric treatment is marvellous. They connect headphones to your head and you go off to sleep for half an hour. On awakening, you feel very fit."

Dr. Winnicott refers to this form of treatment as if it were still in the experimental stage. The fact that it has raised the recovery rate in the depressive psychoses by over 60% should provide sufficient evidence of its efficacy. Indeed, it is generally agreed among psychiatrists that it is almost specific in this form of mental illness. Are we therefore being asked to abandon it merely because it is alleged to be empirical? Is not the statement about "ethical implications" rather suggestive of the literature published by the various antivivisection societies? If it is rational for the profession to oppose such literature strongly, it should also be rational for it to oppose a similar type of propaganda, even when this is initiated by one of its own members.—I am, etc.,

W. LIDDELL MILLIGAN.

City Mental Hospital, Newcastle-upon-Tyne.

SIR,—Dr. D. W. Winnicott (Dec. 25, p. 829) raises an important set of problems. My reaction to them from experience in several hospitals is as follows:

(1) I had always had a lingering fear lest the electrocution chair might be an agonizing prelude to death. After giving a large number of shock treatments my mind is at rest. Complete unconsciousness is instantaneous.

(2) I have found no experienced teachers in any mental hospital. The rationale is not taught and is probably not understood by those who teach the technique. A new man is taught how the machine works, and with the usual warning about weak hearts and full stomachs he is left to get on with the treatment.

(3) At present I know of no body of statistics which have been compiled as to such things as influence on temperature, effect on pupil reaction, mnemonic measurements resulting immediately, and for 24 hours or more, after treatment.

(4) So far as I know there are no records of any observations which have been made over a long series of cases, by which one can learn how to make a diagnosis as to the suitability of any case for treatment, and of the reason why a certain percentage of selected cases improve temporarily, others improve over longer periods, and others show no sign of progress.

(5) The treatment has been so vulgarized by the Press that certain private mental hospitals advertise their use of this treatment as a method of attracting patients. Friends and relatives are beginning to think all is not being done for the patient if shock treatment is not being tried.

(6) In my opinion a start should be made in every hospital where shock treatment is used to build up "a science of shock treatment" by appointing a man with sufficient time and talent to study the whole relationship between patients and the treatment as to the suitability, the reaction, the volume, the length of time, and the post-treatment results which may follow for at least twelve months after a course has been given.

—I am, etc.,

London, W.1.

JOSIAH OLDFIELD.

SIR.—I am afraid I cannot see eye to eye with Dr. D. W. Winnicott's plea for a discussion of the ethical implications of the shock treatment in psychiatry (Dec. 25, p. 829), as it seems to me that there does not exist such a problem if the treatment is administered—as it always ought to be—by the experienced mental specialist only. Any practitioner experienced in the treatment and the psychopathology of mental disorders appreciates the drawbacks of this method, and knows that one cannot cure schizophrenia or even involutional melancholia by merely turning a switch or injecting a chemical compound into the veins. He knows that this is only part of a treatment which must be supported by purely psychological methods such as persuasion, psycho-analysis, and suggestion. He is horrified at the thought that anybody but an experienced mental specialist may feel entitled to try out this method of treatment, which is just as dangerous in the hands of the inexperienced as radium or an anaesthetic in untrained hands.

Although some patients are frightened or feel some vague discomfort during the treatment, no patient is conscious of being hurt by it, and there is not the least suggestion of a suicidal impulse on his part. Neither have any of my colleagues, who have administered hundreds of shock treatments, ever been aware of intending consciously or subconsciously to hurt the patient, and I am convinced that even the most thorough psycho-analysis of all mental specialists administering this treatment would fail to detect any sadistic complexes.

As I have pointed out in a previous letter (Oct. 24, 1942, p. 496), the indications for shock treatment are limited, and the aim of the treatment—cure or relief only—must be kept in mind when selecting the cases. It is surely no panacea and dangerous in the hands of the inexperienced. The conscientious expert, however, need have no troubled conscience as to the ethical justification so long as he keeps in mind that the essence of all mental treatment is psychological. The tremendous success of the electrical convulsion apparatus even in the lay press is undoubtedly due to the old magic of electricity, with its switchboards, wires, and red lights, which acts even in these enlightened times like a potent psychological factor or even with greater charm and power than the injection in a vein and the manipulations of nurses and physician during shock treatment.—I am, etc.,

K. A. GRAF,

Assistant Medical Officer, Monmouthshire Mental Hospital.

### Duodenitis

SIR.—Dr. Wroth's letter of Nov. 27 about duodenitis raises several points of great interest to radiologists.

He asks for a definition of duodenitis. Surely, duodenitis means inflammation of the duodenum, chiefly of the mucosal coat. The inflammatory changes in the mucosa are described by pathologists who have studied suitably prepared specimens.

The indirect signs of such changes are unreliable, and the radiologist should apply himself to the demonstration of the condition of the mucous membrane of the duodenum. He may report that his interpretation of the appearances is that the mucosa is normal, that there is an ulcer niche or

other abnormality present, or that the rugae are coarsened in calibre, irregular in pattern, and stiffened in consistency. Until the latter appearances can be shown to be due to some other condition they must be considered as due to inflammatory changes—i.e., duodenitis.

The fluoroscopic examination permits the study of the movements of a given part, but with modern technique a report on the anatomical conditions is not to be permitted. What is seen on the screen can be and must be recorded on the film. If it is not, the radiologist may, without shame, report that for one technical reason or another he has failed to demonstrate the condition of the mucosa. He must not mislead the clinician by casting a radiological horoscope and interpreting indirect signs as indicating an organic lesion. Rapid emptying of the stomach, spasm of the pyloric antrum, irregular and fleeting filling and inconstant contour of the duodenal cap, are signs of a disturbance of gastro-duodenal motility: they may mask an organic lesion. If the observer cannot find the latter, he is not entitled to infer its presence from the former. This is not the time or place to enter into the differential diagnosis or into technique in any greater detail. Duodenitis, as gastritis, seems to be a definite and defined condition. The frequent diagnosis of such a condition on insufficient evidence brings radiological methods into disrepute.

—I am, etc.,

London, W.1.

G. T. CALTHROP.

SIR.—I am in agreement with Dr. Norman Henderson's remarks (Dec. 25, p. 828) concerning cases in which the outstanding features are spasm of the pylorus and duodenum. I have found that the great bulk of these cases are due to duodenal ulcer. I have no doubt that there is such a condition as "duodenitis," and typical features of this condition with pathological verification have been described by Dr. B. R. Kirklin. I myself have never actually met with one of these cases, but I should imagine that they are similar to the cases of chronic duodenitis mentioned by Dr. Henderson.

There is one point upon which I should like to comment, and that is in relation to the ulcer crater. Dr. Henderson says that only a small percentage of duodenal ulcers present a demonstrable crater on x-ray examination, and that the large proportion of those showing craters have a history of long standing. This statement of his, perhaps, needs some modification. Akerlund in his series of cases found a crater in 60% and Berg in 50%. Geyman in America found it in 40% in his first series, and in a later series 60% of all cases. In an investigation of cases at Manchester Royal Infirmary I found it in 42% of all cases diagnosed as duodenal ulcer. These figures are rather higher than a "small percentage." Apart from this, in 117 cases showing a crater 11 had no deformity of the cap or irritability and 37 showed only a slight degree of deformity. In fact, a crater was shown in 48 out of 90 cases having slight or no deformity (i.e., 53%), and in only 12 out of 47 cases with severe deformity (i.e., 25%). This shows that the crater is more often found in earlier cases than in those with a long history, as these 90 cases all had histories under five years. Certainly, no radiologist would wait until he found a crater before diagnosing a duodenal ulcer; but it is, when found, a very valuable sign, more so in early cases, and may be the only sign of an ulcer. It is therefore in early cases that it should be particularly searched for.—I am, etc.,

Wrexham.

STANLEY NOWELL.

### X Rays and the Clinical Society of London

SIR.—In reply to Sir Arthur Hurst's letter (Dec. 18, p. 795), my authority for the statement that the most interesting event in the history of the Clinical Society of London was the first medical description of x rays in this country was Sir William Hale-White, who was honorary secretary of the Society in 1893-6, and in a letter to the *Lancet* (1930, 2) said that "we owe to Prof. Thompson the first medical demonstration of x rays in this country." My attention had been drawn to this letter by a note in Lady Burdon Sanderson's memoir of her husband (1911, p. 73), who, besides many other distinctions, was the first honorary secretary of the Clinical Society.—I am, etc.,

Kensington, W.8.

J. D. ROLLESTON.

## Obituary

GEORGE CRANSTON ANDERSON, C.B.E.,  
M.D., LL.D., F.R.C.P.

Secretary, British Medical Association

We announce with sorrow that George Anderson, our dear friend and honoured colleague, has died in hospital ten weeks after the severe heart attack which overtook him on Oct. 23.

From the time it was founded by Sir Charles Hastings (who was its first General Secretary as well as its first Chairman of Council) the British Medical Association has been fortunate above all things in its leaders. This remark applies not only to the long list of men who have occupied its principal chairs or sat at its treasury but to the shorter succession of its chiefs of staff. No three men could have been more diverse in gifts, outlook, and temperament than the three who have borne the title of "Medical Secretary"—Sir James Smith Whitaker, Dr. Alfred Cox, and Dr. G. C. Anderson—yet each of them during his term of office and in the situation which he had to face came to be accepted as the embodiment of the B.M.A. In each case the name of the Association and of its chief executive official were for the time being interchangeable terms.

(Elliott and Fry)

When Alfred Cox retired from the Medical Secretaryship in 1932 there were many who felt that, efficient and popular as his successor would assuredly be, he could never fill the place occupied by Cox. The man who had been Cox's trusted deputy for thirteen years certainly presented a complete contrast in appearance and manner to his old colleague. But he found his way into the confidence and affection of the rank and file as assuredly as did his predecessor. The good B.M.A. executive officer is not fashioned from a single mould.

The career of George Cranston Anderson was so closely bound up with the Association from the time of joining its headquarters staff when he was not yet forty that one was inclined to forget that he had already ten years in general practice, followed by three years on active war service in Egypt.

Palestine. He was born on Nov. 14, 1879, the only son of a Scottish minister, the Rev. K. C. Anderson, D.D. The father was a native of Jedburgh, who early in life held several pastorates of Congregational churches in the United States, and came back to this country to the charge of a church at Bradford, and eventually to one at Dundee. He was one of the leaders in the liberal theology controversy of forty years ago. Cranston was the family name of his mother. The son went to Edinburgh University, where he was famous as an athlete, took his M.B., Ch.B. in 1904, and proceeded M.D. in 1909. For several years he won the university championship over the hurdles, the long jump, and the high jump; he was also for a year Scottish amateur champion hurdler. After a period as house-surgeon at Clayton Hospital, Wakefield, he returned North and settled in practice at Methil, a coast village in Fife, in 1906. He served also as medical superintendent of the Wemyss Memorial Hospital near by.

Always a most likeable man, with charm and grace of manner, he soon became known and esteemed among his colleagues in the Fife Branch, which from its formation was an active and influential unit in B.M.A. affairs, especially during the troubles which accompanied the inception of National Health Insurance. About 1911 Anderson became honorary secretary of the Branch and a member of the Scottish Committee. He was secretary also of the Panel Committee, and, when the first European war broke out, of the Local Medical War Committee.

The war, however, presently took him away from the coast of the Firth of Forth to the banks of the Nile, where he served as surgical specialist to the 69th General Hospital. Soon after his return in 1919 he was called to the Deputy Medical Secretaryship of the Association. His colleagues in Fife mingled their regret at the severance with their pride in the fact that "Anderson of Denbeath" should have been given this opportunity of helping to shape medical policy in the post-war world. They gave him a presentation of silver plate and expressed their affection for him and their respect for his qualities.

At the time George Anderson entered on his work at the former London home of the Association, 429, Strand, the war machine was, going into reverse. The work of the Central Medical War Committee, which had absorbed so much of the energy of headquarters for four strenuous years, was now directed in the main to help in individual cases of hardship on demobilization. The rumblings of the National Health Insurance controversy, silenced during the war, began to be heard again, though the note was different. The Insurance Acts Committee under the brilliant leadership of Dr. (afterwards Sir Henry) Brackenbury was engaged on the formidable task of consolidating the new service so that it yielded the greatest public good, and of endeavouring so to improve the terms and conditions as to yield as much satisfaction as possible to practitioners. The secretaryship of the committee fell to Anderson's lot; it called for an immense amount of complex administrative work, and it was said of him that he knew the Insurance Acts and Regulations from end to end. Those were days when the Panel Conference met generally twice in the year and sat until midnight. Negotiations over terms of service were opened up with the most intractable of Ministers of Health, Sir Alfred Mond, afterwards Lord Melchett. Anderson did great service in preparing the Association's case at the first court of inquiry into the capitation fee, presided over by Sir Thomas Hughes, and the evidence for the subsequent Royal Commission. Even after he had become full Medical Secretary he retained his post at the right hand of the chairman of the Insurance Acts Committee, not, as he explained, because he lacked faith in his juniors, but because he felt that in a period which continued to be difficult it was an advantage to have someone who had had experience of previous negotiations. He was also identified with the work of the Science, the Ethical, and the Hospitals Committees, and took a share in formulating the hospital policy, a tedious but necessary piece of business undertaken in the early 'twenties.

Two excellent pieces of organization which lay outside the main stream of the Association's work and which owed a great deal to Anderson's enthusiasm and statesmanship were the National Eye Service and the National Register of Medical Auxiliaries. His secretaryship of the Ophthalmic Committee led on to an active share in the National Ophthalmic Treatment Board, which organized the National Eye Service in 1929. The National Register was established, after difficult negotiations, in 1933; he was a member of the Board of Registration, and took immense pains over a very delicate piece of work. Never did he lose in the grind of routine the zest for new achievement. He entered with vigour into the fight which the Association undertook in the Select Committee of the House of Lords against the proposal to register osteopaths. At every sitting of that committee there he was, conferring with the distinguished counsel who appeared for the Association, and marshalling the medical evidence. But in fact the later career of Anderson is the history of the Association. In deputations to Ministers, in innumerable conferences, in round-table discussions with representatives of other medical bodies, of hospitals, of trade unions, as well as in the routine business of the Council and its committees—committees which seldom sat for less than three hours—he was always the chairman's aide-de-camp, the spokesman's prompter, the man who attended to things, and when himself called upon to speak, always modestly firm and persuasive, and generally getting his way.

It was in 1932, following the Centenary celebrations, that he succeeded Dr. Cox as Medical Secretary. He had long been marked out for that promotion. Five years later, after reorganization at the head office, he became Secretary, the prefix "Medical" being dropped. This only meant that to his former duties and responsibilities were added many others on the business side. It must be remembered that in addition to

its more ordinary activities the Association is a considerable landlord and a large employer of labour.

In 1935 came the memorable meeting at Melbourne and the World Tour. The genius of Anderson for creating a spirit of good fellowship contributed to the success of the occasion, and after the voyage a number of members of the party publicly acknowledged his "untiring courtesy and helpfulness." A more serious and exhausting mission awaited him in the winter of 1936-7, when he was sent to India in order that the Council might have first-hand information of the conditions of practice there. In less than three months he travelled over 10,000 miles on the Indian railways, visited 19 cities in 11 provinces, saw something of the principal medical colleges and a number of the schools, and obtained an insight into all forms of Indian medical practice. The members of the profession in India were greatly stimulated by the addresses he gave. One of his hosts in the Punjab said that before he came a very general remark among the members was, "The B.M.A. has done nothing for us," but after he had gone the remark was altered to, "We are the B.M.A." George Anderson was certainly the most travelled official the Association has ever had. In addition to visiting various cities on the Continent as the representative for Britain on the Association Professionnelle Internationale des Médecins, another long tour was undertaken early in 1939, when he visited the West Indies. The purpose of this journey was partly to enable him to recuperate after a protracted illness and partly to encourage the West Indian Branches. He visited Barbados, Trinidad, Grenada, and Jamaica, and was warmly welcomed by gatherings of members in each place.

The outbreak of the second European war brought to him a period of strain comparable only with that experienced by members of the Government and the heads of the Civil Service and the fighting Services. In the recruitment of doctors for the Forces, in holding the balance between civilian and military requirements, in endeavouring to redistribute doctor-power so as to meet the situation brought about by evacuation and large transfers of labour, his energy, tact, and wisdom were constantly at call. The Emergency Medical Service, the Protection of Practices Scheme, and various other pieces of organization, hurriedly called into being, required daily attention and looking ahead. He was the natural target for multitudes of questions, down to such matters as the allowance of petrol for a doctor's car or the calling up of a doctor's maid-servant, and often a case which related only to one individual would necessitate a long correspondence and perhaps interviews. All this had to be done with a staff depleted of many experienced workers and recruited from the inexperienced.

Even while this wartime burden was being carried, and was actually expanding, there came the need to plan for the post-war period. The Medical Planning Commission was set up and issued its interim report. Then came the Beveridge report and the invitation from the Minister of Health to form a Representative Committee for conversations on the shape of future medical services. The implications of that invitation were instantly grasped and acted upon by Anderson. His statesmanship was again shown in the lead he gave, particularly in addresses in Manchester, Edinburgh, and Glasgow in the summer of 1943, entitled "Evolution, not Revolution," which steadied the position and influenced the discussions in the Association on the principles of the future service in anticipation of the Government's White Paper. But these multiplied labours, with an eager spirit which would permit no slackening and a physical frame which in recent years was far from robust, contributed to the serious breakdown in health which followed the Annual Representative Meeting of 1943.

To the good secretary no detail of his work is trivial. Anderson never became so absorbed in central concerns as to neglect the periphery. In normal times he took his full share of visits to Divisions, often involving long travelling, perhaps by night, to address the faithful few who turned up, unless, of course, some crisis brought an overflowing attendance. But his not over-prepared addresses, like his "Occasional Letters," carried an influence out of proportion to their rather incidental character. With the honorary secretaries of Divisions and Branches he cultivated a fraternal attitude. He knew their difficulties, having been an honorary secretary himself. He once expressed his dislike of letters which began, "I am sorry to trouble you": he was there, he said, to be troubled. To

those who served under him at headquarters he was a considerate chief, always ready to make public acknowledgment of the good work of his juniors, and to give any buried talent an opportunity for emergence. But he possessed also a sense of humour and something of a philosophic detachment, and it was refreshing to catch the twinkle in his eye when a committee—or some members of it—was taking itself too seriously. Not that he ever lost dignity; an easy dignity came naturally to him, and a fine and agreeable presence marked him out in any assembly.

Of the Association and its ideals he was a zealous champion. Any attack upon it in the Press or elsewhere, or any misconstruction of its action, drew from him a reply which was all the more cogent for being so courteously expressed. He often lamented that, somehow, the good work that the Association was doing remained unknown to the mass of Association members and to the public.

In 1935 he was awarded the King's Jubilee Medal. At the Belfast Meeting in 1937 the Hon. LL.D. of Queen's University was conferred upon him. In the speech at the graduation ceremony he was described as one who had "brought to the consideration of the questions which concerned the Association an alert and balanced mind, in sympathy with the difficulties of the general practitioner, but determined also to see that medicine was so organized as to function with the greatest possible efficiency in advancing and maintaining the health of the community."

In 1941 he was elected a Fellow of the Royal College of Physicians of London under the special by-law, and in January, 1942, he received the Commandership of the Order of the British Empire. His home life was ideally happy, and with Mrs. Anderson, who accompanied her husband on many Association occasions, including his long tours on Association business, the deepest sympathy will be felt among a wide circle of friends in the profession and far beyond it.

#### Personal Tributes

Sir KAYE LE FLEMING writes:

The news of the death of the Secretary will come as a shock and arouse a sense of grievous loss and concern in the minds of all members of the Association and, indeed, of most members of our profession. Few outside the Council were aware of the grave anxiety felt for his health since his sudden breakdown in October. Only those with inside knowledge of the organization at B.M.A. House can appreciate the great strain borne by the Secretary, especially during the last few years, and his determination not to spare himself in the effort and responsibility which his post involved. No one could persuade him to take the break from work necessary to meet the strain on his health, and his manner and appearance helped to disguise the heavy calls he was making on his strength. It may truly be said that George Anderson gave his life to the Association and his profession.

Anderson came to the B.M.A. just after the last war, at a time when the Association was suffering from the setback of the introduction of the National Health Service followed by four years of war. He succeeded Dr. Alfred Cox in 1932, and lived to see the membership of the Association more than doubled, a steady increase of more than one thousand members for each year of his connexion with headquarters. His trip to Canada in 1930, his management of the "Round the World Tour" in 1935, his special visit to the West Indies, and to India in 1937 made him a familiar figure to the leading members of our profession throughout the British Empire and in America. Everywhere he carried with him the capacity of associating his organizing professional duties with the personal charm which endeared him to all he met. Surely no other member of our profession could ever count such a host of friends and admirers. The full share of the increased influence and prestige of the Association which we owe to him will take time to appraise and appear in proper perspective, but his name will be indelibly inscribed in our history.

It is not easy to pay tribute to the many qualities that helped to make Anderson the outstandingly successful man he was. The alert upright figure, the easy conversational gifts and charm of manner attracted at once. His power of rapid concentration on successive diverse problems, combined with an

inexhaustible capacity for work, astonished even those who continually shared his labours. Easy of approach, he had the great gift at his command of mixing with all men. In delicate negotiations with Government Departments, however difficult, he never made an enemy. In public speaking clear and to the point, delivered with sincerity and dignity and with just the right touch of humour when required, he always pleased his audience. Those who were closest to him in his work would perhaps place highest in the list of his gifts the sure perception of principles of policy and his foresight in preparing for future changes which appeared to him inevitable.

Much more could be said, and will be said, ere justice is done to so fine an example of our profession. Anderson is gone, and at the very moment that we need him most. The B.M.A., the profession, and the public are the poorer by his loss. Our great organization has received a shock which for the moment leaves it stunned. Without him our resources to meet the crisis that lies ahead will be severely taxed, but we shall never forget the hand that has guided us so far with success.

To Mrs. Anderson will go a wave of sincere sympathy, and from all those members in particular who remember the graceful part she played in the big social events of our Annual Meetings.

Dr. H. GUY DAIN, Chairman of Council, writes:

To those who have known him since his appointment to the Association, the B.M.A. without George Anderson does not seem possible. No association ever had a more single-minded servant. The B.M.A. may be said to have been both his work and his hobby. Its interests were never out of his thoughts, and he was always planning for its advancement. And with what success its growth during his Secretaryship, with the increasing influence of the Association, both in the social life of the country as well as among doctors, is eloquent testimony. He really did live for the B.M.A. His boundless energy was always at the service of the Association. As Secretary to the Insurance Acts Committee, in earlier years, and all through his office, his work to improve the insurance medical service and the conditions of insurance practitioners has been continuous, and is fully recognized by all. An outstanding example of his foresight and statesmanship is the present Central Medical War Committee. While war was yet an uncertain threat, he was responsible for setting up a card index of all registered practitioners with their qualifications, experience, and ability to undertake war work. This index was completed and ready for immediate use for the recruitment of doctors as soon as war broke out, and has been of inestimable value to the country as well as to doctors.

And of Anderson the man. Those of us who have known and worked closely with him for so long, are mourning a dear friend. One to whom we could always take our problems, and certain of a good-tempered and sympathetic reception, and help in the solution. One of the attractions of attending a meeting in London was the opportunity of a talk with George before and after the meeting. His cheerful friendliness and welcoming smile will always remain. And outside the B.M.A. he did enjoy his golf and his game of bridge.

His memory will live on. The Association will reap the reward of his labours in the years to come. In future days, as the results of his work are incorporated in the machinery of the medical profession, there will be many doctors who with grateful hearts will want to say, "Thank you, Anderson." The whole Association mourns with Mrs. Anderson.

Mr. H. S. SOUTTAR writes:

Only those who have worked closely with Anderson in the last few years can realize what the British Medical Association and the whole country have lost. He had become so essential a part of every phase of our professional organization that it is difficult to think of it apart from his inspiring personality. For years he has been our ambassador at the Ministry of Health, and few decisions were reached without his advice. The Planning Commission was his own idea, and to him we owe the co-ordination of our whole profession which has resulted largely from its work. The Medical War Relief Fund was established at his suggestion. But his great achievement has

been the organization of recruitment of our profession for war, of the whole of which he was the very pivot and mainspring. On the Priority Committee, the Central Medical War Committee, the Services Committee, and on all the ramifications of the intricate problems involved, he worked with untiring energy, with no thought of the cost to himself.

In the arduous days which lie ahead we shall sadly miss his wisdom and his enterprise, but those who follow him will reap the reward of his great labours. Beyond any question he has sacrificed his life in the service of his country, but not before he had laid the foundation of great future progress. He has set before us great ideals, and to follow them is the highest tribute we can raise to his memory.

Dr. MONTAGUE SYDNEY WOOLF, who died in America on April 20 last, was born in Plymouth and received his early education in Birmingham, after which he spent a year at Bonn and Heidelberg with a scholarship in modern languages. But his true calling was medicine, which he studied at University College Hospital, London, winning a scholarship in anatomy and physiology and medals in pathology and clinical surgery. He qualified M.R.C.S., L.R.C.P. in 1914, and during the last war served with the R.A.M.C. and in the British Naval Transport Service. After the close of the war Dr. Woolf settled in San Francisco, where he became resident surgeon at the University of California Hospital. In 1925 he visited London for postgraduate study in proctology. His publications were largely on matters connected with that specialty, but he also wrote a textbook *Principles of Surgery for Nurses*. In an obituary notice appearing in *California and Western Medicine* Dr. Richard W. Harvey has paid tribute to Dr. Woolf's gentleness, devotion, and friendliness.

We regret to announce the death on Dec. 23, 1943, at Haslemere, Surrey, of Mr. ARTHUR HENRY WILLIAM HUNT in his 78th year. He studied medicine at the Westminster Hospital, where he won a scholarship, and took the L.R.C.P. diploma in 1888 and the M.R.C.S. in 1889. After serving as house-surgeon at the Westminster he began his long connexion with the Royal Hospital, Wolverhampton, as house-surgeon, later becoming honorary gynaecologist and a member of the visiting surgical staff. On his retirement the governors of the hospital elected him consulting surgeon. He held a commission as captain R.A.M.C.(T.) during the last war, and was awarded the M.B.E. in 1920. In 1925 Mr. Hunt gave up active work and went to live in Surrey. He had joined the British Medical Association in 1893 and was chairman of the Guildford Division 1931-2. In recognition of his work for the profession during many years of practice in the Midlands the Birmingham Branch elected him an Associate Member.

Dr. JOHN HARVEY KELLOGG, who died last month at Battle Creek, Michigan, towards the close of his 92nd year, combined a number of diverse qualities which made him almost a legendary figure. First and foremost he was a health reformer, with ideas much in advance of his time; he was beyond question a philanthropist; he had keen business sense and ability, coupled with a gift for showmanship; and his dominant personality and unflagging zest for life were part and parcel of the wonderful physique which bore him along into advanced old age with his faculties in full working trim. In matters of regimen Dr. Kellogg practised what he preached for 70 years; he was a walking testimonial to the rules of health which he had laid down for the inmates of the Battle Creek Sanitarium and which he spread far and wide through his magazine *Good Health*. Almost up to the end he was hard at work, with his chief dietitian, on a *Vitamin Cook Book*, bringing his ideas on nutrition and dietetics into line with modern knowledge. On his 90th birthday (Feb. 26, 1942) he received messages of congratulation from people of the highest standing in the U.S.A., and the citizens of Battle Creek gave him a framed address and a banquet in honour of "one who loved his fellow men." Dr. Kellogg graduated M.D. from the Bellevue Hospital Medical College, New York, in 1875, and his lifelong work in and for the sanitarium began as a temporary one-year job. Later he launched the cereal food business which made his name a household word. People from many other countries went to his institution for a complete physical overhaul; others spent their holidays at Battle Creek as out-patients, following a prescribed course of diet and exercise and attending the clinic for practical guidance. In his younger days he often toured Europe, visiting medical centres in Rome, Vienna, Paris, London, Berlin, and Petrograd, picking up ideas to put into practice at Battle Creek.

## The Services

The D.S.O. has been awarded to Major (temp. Lieut.-Col.) P. R. Wheatley, R.A.M.C., and the M.C. to Capt. (temp. Major) J. B. McEwen and Capts. G. Rieby-Jones and J. Rutherford, R.A.M.C., in recognition of gallant and distinguished services in Sicily.

Surg. Lieut.-Cmdr. R. G. Reid and Acting Surg. Cmdr. E. G. Thomas, R.N.V.R., have been awarded the R.N.V.R. officers' decoration.

The following appointments and mentions in recognition of distinguished services in Persia and Iraq have been announced in the *London Gazette*:

C.B.E. (Military Division)—Major-Gen (temp) J G Gill.  
D.S.O., O.B.E., M.C., late R.A.M.C.

O.B.E. (Military Division)—Col. (temp) W. H. A. D. Sutton,  
R.A.M.C.

M.B.E. (Military District).—Capt. (temp Major) M S Boparai.  
I.M.S.

*Mentioned in Dispatches*—Major (temp. Lieut.-Col.) W. A. D. Drummond, Major D. J. O'Ryan, Capt. T. Ronai, R.A.M.C., Col. (temp.) K. S. Master, M.C., Capts. (temp. Majors) J. H. Bowie, and J. S. Gill, and Subadar G. Durair Krishnan, I.M.S.

The London Gazette announces the appointment to M.B.E. (Military Division) of Fl. Lieut. S. T. Winter, R.A.F.V.R. The announcement reads as follows:

When rescue for an operational sortie on 14 July 1943, a Stirling bomber crashed while attempting an emergency landing. The bomber burst into flames. Fl. Lieut. Winter, who was the medical officer on duty immediately proceeded to the scene. Regardless of his own safety, he immediately strove to escape and entered the burning fuselage in a vain endeavour to release the mid-upper gunner, who was trapped upside down in his turret. Despite the flames and heat, Fl. Lieut. Winter then attended to the needs of the injured members of the crew. Throughout he displayed high courage and devotion to duty.

The *London Gazette* has announced the appointment as M.B.E. (Military Division) of Temp. Surg. Lieut. G. D. Taylor, R.N.V.R., for services to the injured after an explosion at sea.

## CASUALTIES IN THE MEDICAL SERVICES

*Died in East Africa.*—Capt. J. B. C. Murdoch, R.A.M.C.

Killed.—Lieut. V. L. Cooper, R.A.M.C.

*Killed in action.*—War Subs. Capt. J. E. T. Munn, R.A.M.C.

**Wounded.**—War Subs. Capt. D. J. Fraser, L. C. Montgomery, M. I. Robinson, and B. C. Rowlands, and Major J. D. Sprague, R.A.M.C.

## DEATHS IN THE SERVICES

We regret to learn that Lieut.-Col. DONALD UYEDALE OWEN, M.D., R.A.M.C., has died in Africa as the result of an illness contracted while on active service. He was honorary physician to out-patients at the Liverpool Royal Infirmary and held various other clinical appointments after winning many academic honours. S. B. H. writes: Donald Owen was in the tradition of, and succession to, a long and of medical men of Welsh extraction who have enriched the profession on Merseyside during the past three decades. Their enduring qualities of strong humanity and kindness of nature, combined with medical skill, were possessed to the full by Donald Owen, and his passing after a relatively short but busy and successful career as a physician will leave a sense of personal loss with his very many friends. As a friend since student days, may I pay tribute to one whose influence and example I, with many more of his friends and colleagues, will carry with me as a lasting memorial.

## Universities and Colleges

## UNIVERSITY OF CAMBRIDGE

At a Congregation held on Dec. 11 the degrees of M.B., B.Chir. were conferred by proxy upon J. R. Handforth.

The following candidates have been approved at the examinations indicated:

**FINAL M.B.—Part I (Surgery, Midwifery, and Gynaecology):** M. S. Adams, C. Attenborough, H. H. E. Batten, T. S. L. Bewick, P. Blaxter, A. Brazier, D. W. Burnford, J. L. Brown, J. L. Cart, R. Clouai, A. C. Compton, N. C. Cooper, P. D. B. Davies, C. D. Drew, E. C. Dyson, R. D. England, D. A. W. Edwards, F. H. Epstein, D. M. Evans, J. J. Fleminiger, M. A. Floyer, P. W. Friedlander, J. W. Fullerton, S. A. M. Harclan, H. M. Giles, M. T. Gillies, M. L. Graeme, C. R. H. Green, J. A. Hartington, C. E. Hartley, G. Hartnidge, F. N. Hicks, I. S. Houghton, B. Holmes, N. S. Hooper, G. J. C. Inman, C. Irving, D. James, C. K. Keane, A. L. McKelvie, R. M. MacPhail, I. A. Magness, M. Lytle, B. Mellroy, T. D. Mort, M. W. L. Mutch, K. N. V. Palmer, T. J. S. Patterson, C. R. Payne, P. B. Philip-Smith, P. D. G. Pugh, K. E. E. Read, T. J. Rendle-Shoof, J. Roche, L. J. Rowley, R. Roxburgh, J. St. John, D. Schofield, D. Schofield, J. A. Shiers, F. N. Siddlebottom, J. Symonds, J. W. E. Tillet, J. C. H. M. Tilden, R. G. Turner, D. Vanstone, D. G. Veater, N. T. Welford, D. P. Whearely, P. Winberg, R. A. Womersley, K. A. A. Wray, G. S. Yeoh,—K. A. C.

Dowen, P. J. Croop, M. Farquharson, R. C. A. Hunter, E. M. Kingsley-Pillars.  
S. M. Martin, L. Predigerast, K. M. E. Reaney, H. F. Seab-Monsterey.  
M. M. Tunstall-Behrens, B. J. Smith.

*Part II (Principles and Practice of Physics, Pathology, and Pharmacology):*  
D. Amble, F. Ashio, V. L. Bullington, A. J. Briggs, L. L. Bromberg,  
C. Carpenter, K. Chnuv, F. A. L. de Cunha, M. P. Durham, J. W. Evans,  
J. Fisher, W. Foreman, J. A. Hallinan, M. Hemming, R. F.  
Hobson, M. D. King, W. Knowles, J. B. Lyon, D. A. Mitchell, R. G. F.  
Parker, M. B. Paul, W. R. Probert, T. Rendle-Short, B. W. Rhodes, L. J.  
Rowley, I. A. Roxburgh, F. A. R. St. John, A. N. Smith, D. Soltau,  
P. G. Somerville, R. G. Tasker, J. H. M. Tilley.—M. K. E. Reaney.

## UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN MEDICAL RADIOLOGY.—Olga Bauerova, Phyllis Burville-Holmes, Elspeth M. Ledlie, M. G. Magan.

## UNIVERSITY OF BRISTOL

The following candidates have been approved at the examinations indicated:

CU M—Marjorie O Dunster  
Final M.B. CU B—(Mrs.) Rukmini L. Ashley, Janet Baker, C. K. Bridge  
Margaret P. Drew, J. Eskell, E. C. Hamlyn, Beryl M. Hinckley, P. A.  
James R. Maggs, (Mrs.) Margaret Pardoe, (Mrs.) Marjorie J. Williams. In  
Group I (completing examination) Elizabeth N. R. Wilson.  
Distinction in Public Health.

## UNIVERSITY OF SHEFFIELD

The following candidates have been approved at the examination indicated:

Final M.B., Ch.B.—*Parts II and III*: R. H. Canter, B. S. Crawford & Ellison, H. Hardy, Margaret S. Hunt, L. A. Storer, Helen M. H. Twidle

QUEEN'S UNIVERSITY, BELFAST

The following candidates have been approved at the examinations indicated:

M-D J. W. Mylitta (with gold medal), T. G. Milken,  
M.B., B.Ch., B.A.O., J. Dando Corkin, J. E. Macdon, J. H. Johnston  
K. G. Malcomson, Margaret Mitchell, J. H. Mick, Pinkerton, H. M.  
Evenson, A. P. S. Ainley, W. J. Allen, M. W. J. Boyd, M. Brown, W. L.  
Lawrence, J. F. J. Campbell, R. D. G. Cowden, R. D. G. Creery, Esther N.  
Davis, W. S. Davis, J. Donaghy, R. J. Donaldson, J. Ferguson, S. I. Gibson  
M. Glass, F. G. Groot, D. G. F. Hamilton, F. Jackson, J. Jefferson  
Gordon, K. Ray, R. S. McLean, G. G. McDowell, C. McGinnis, A. I.  
Mathewson, T. F. B. Minford, J. Mitchell, T. M. Routfen, N. Sanderson  
Smith, Marion G. Summ, C. M. Taggart, Adeline H. Thompson, I. G.  
Atchman, Margaret R. Wilson.

SOCIETY OF APOTHECARIES OF LONDON

At a recent meeting of the Court of Assistants, with Sir Stanley Woodward, Master, in the chair, Surg. Rear-Admiral C. P. G. Wakeley was elected to a seat on the Court, and Mr. Ernest Busby was appointed Clerk to the Society.

The following candidates have satisfied the examiners in the subjects indicated:

PATHOLOGY, BACTERIOLOGY, AND FORENSIC MEDICINE—P. L. Bransvig, J. L. Brennan, D. E. M. Brown, N. J. Caldwell, D. Cappon, K. R. J. Coster, V. G. Dawson, E. L. Dutt, R. J. H. Hodges, F. R. S. Knight, P. E. Kars, D. A. Tait, E. G. Wright, S. Yaffe.

SURGICAL—A. W. Banks, A. E. Bernstein, J. L. Brennan, D. E. M. Brown, G. Martin, J. Middleton, D. A. Tait, A. G. Wolstenholme.

MEDICINE—A. W. Banks, D. E. M. Brown, P. V. G. Dawson, R. K. Asham, F. R. S. Knight, E. Mars, C. P. P. Nair, D. A. Tait, E. G. Wright, J. Middleton, A. L. S. Brown, D. Cappon, P. V. G. Dawson.

PHYSIOLOGY—F. Fiducia, J. H. Hodges, M. W. Johnston.

The diploma of the Society was granted to C. M. F. Fiducia and S. Yaffe.

## Medical Notes in Parliament

**Mass Radiology Units for Over-seas.**—Dr. MORGAN asked on Dec. 14 whether any steps had been taken to secure durable, transportable mass radiology sets and trained personnel for use in the various Colonies. Col. STANLEY replied that the supply position was such that at the present time it was not possible to arrange for a satisfactory type of mobile unit for use in tropical conditions to be built in this country. The position was kept under review.

**Immunization against Tuberculosis.**—Dr. SUMMERSKILL inquired Dec. 16 what action the Minister of Health was taking following request from the Tuberculosis Association that recognition should be given to the importance of immunization against tuberculosis. Mr. WILLING said he knew the Tuberculosis Association had been drawing attention to this subject. Immunization against tuberculosis is still surrounded by numerous difficulties, but he was arranging his officers to discuss the whole matter with representatives of the association.

**Treatment of Arthritis.**—Mr. WILLINK told Major Lyons on April 16 that the cause and treatment of arthritis continued to receive the active attention of the Empire Rheumatism Council, whose last report was published in December, 1942. Research into causation of arthritis was restricted by the lack of any promising fresh line of approach. New methods of treatment were tried as they became available. Life insurance was not available to patients, and the cause of the disease was not as yet known. The only treatment being made in the United States was the use of the efficacy of electrically activated ergosterol. He was making inquiries as to the position in the United States.

**Silicosis Claims.**—Mr. HERBERT MORRISON said on Dec. 17 that since July 1 the medical board had received 2,213 applications from South Wales coal-miners under the Various Industries (Silicosis) Scheme, 1931, or the Coal-mining Industry (Pneumoconiosis) Scheme, 1943. In 1,282 of these cases the board had not yet come to a decision. As from July 1 last the strength of the medical board in South Wales was doubled, and further assistance was being given so far as was practicable. Claims on the medical profession at the present time made it very difficult to secure the services of qualified men who could devote time to this work, and some delay was unavoidable.

#### Notes in Brief

Thirty-two British prisoners of war recently repatriated from Germany were classified as suffering from mental and nervous affections justifying repatriation. The number of prisoners of war in Germany classified as suffering from mental ailments was small.

## EPIDEMIOLOGICAL NOTES

### Discussion of Table

In *England and Wales* there was a large fall in notifications during the week: scarlet fever down by 628, acute pneumonia by 363, whooping-cough by 241, diphtheria by 84, dysentery by 33, and measles by 28.

Influenza deaths in the great towns numbered 1,109, or 39 fewer than in the preceding week. (Returns for the week ending Dec. 25 show that influenza deaths are down to 690.) The largest number of deaths registered during the past five weeks were in London 366, Birmingham 211, Manchester 207, and Liverpool 137. Liverpool was the only one of these cities for which an increase was recorded during the week ending Dec. 18.

During recent weeks scarlet fever, whooping-cough, and measles have been steadily declining in incidence; measles is at its lowest level since registration began in 1939. The drop in acute pneumonia was greatest in the North, the largest falls being in Yorks West Riding by 117, and in Lancashire by 70.

The chief centres of dysentery were London 47, Essex 13, Lancashire 15.

In *Scotland* similar trends are noticed. The largest falls were 75 for whooping-cough, 77 for scarlet fever, and 47 for diphtheria. Cerebrospinal fever, diphtheria, and scarlet fever were at their lowest incidence since last summer.

In *Northern Ireland* scarlet fever rose by 30, and 67 of the 116 cases were notified in Belfast.

### Diphtheria

The seasonal distribution of diphtheria has been well marked in recent years, with an incidence during the winter of approximately twice that of the summer. The seasonal rise in England and Wales during the present year has not been as distinct, and the decline in the number of notifications during the past five weeks is in contrast to experience of similar periods. It appears that the campaign for immunization has at last begun to have an effect on the incidence of diphtheria. The notifications, summed in five-week periods, compared with the immediately preceding years are:

Weeks	1943	1942	1941	1940	1939	1938	1937
1-5 ..	4,286	4,736	6,057	3,666	6,278	8,726	6,225
6-10 ..	4,121	4,341	5,349	3,409	5,795	7,886	5,782
11-15 ..	3,835	4,083	4,938	3,414	4,381	6,733	4,927
16-20 ..	3,264	3,460	4,500	3,402	3,981	5,170	4,646
21-25 ..	3,043	3,216	4,391	3,568	3,718	4,735	4,774
26-30 ..	2,960	3,515	4,150	3,924	4,350	5,043	4,776
31-35 ..	2,708	3,350	3,639	4,056	3,756	4,745	4,518
36-40 ..	3,610	4,363	4,728	5,315	4,363	5,945	6,638
41-45 ..	3,710	4,620	5,001	6,522	4,782	6,933	8,385
46-50 ..	3,222	4,966	5,459	6,925	4,891	7,562	8,466

The notifications are now only 66% of those for the corresponding period of 1939, the lowest of the recent corresponding periods. The actual position may be more favourable than the returns indicate, since there has been a large increase in the error of diagnosis. This error in the immediate pre-war period was of the order of 30% in London, but lately it has been in the neighbourhood of 50% in the experience of some hospitals, and it is probable, although no figures are available, that this increase is general throughout the country. General practitioners will no doubt feel encouraged by the figures given to back up for all they are worth the campaign so successfully begun by the Ministry of Health.

### The Week Ending December 25

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,786, whooping-cough 1,244, diphtheria 498, measles 363, acute pneumonia 2,079, cerebrospinal fever 53, dysentery 96, paratyphoid 1, typhoid 2. Deaths from influenza in the great towns numbered 690.

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 18.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

\* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth death rates for Northern Ireland are no longer available.

# ERGOMETRINE B.D.H.

*The water-soluble alkaloid of ergot with a reliable and rapid action*

Ergometrine has been used 'in cases of threatened severe post-partum hæmorrhage, both before and after delivery of the placenta, in preference to pituitary extract, and . . . found . . . vastly superior in action in both rapidity and degree to the time-honoured product' (Brit. Med. Journ., Jan. 6th, 1940, p.33).

Ergometrine B.D.H. should be used as a routine after parturition in order to produce the classical effect of ergot. It is both potent and stable.

*Details of dosage and other relevant information will be gladly supplied on request.*

TRADE MARK  
'SVC'  
BRAND  
acetarsol vaginal compound  
in leucorrhœa

In the treatment of leucorrhœa associated with the presence of *T. vaginalis*, formerly so intractable a condition, 'SVC' brand of acetarsol vaginal compound is frequently effective. The product is available in two forms; tablets of elongated shape for insertion and powder for insufflation. In response to a number of requests the volume of the latter has recently been doubled, the acetarsol content remaining the same. Vaginal insufflations are contraindicated during pregnancy.

'SVC' is available in containers of 25 tablets 4s. 0d., containers of 100 tablets 12s. 0d., and in powder, in containers of 6 x 6 Gm. 8s. 6d. (Less the usual discounts and plus purchase tax). Obtainable through your usual supplier.

Our Medical Information Department will be glad to supply you with further details.

# Vitamin Therapy and Influenza

## AVOIDING COMPLICATIONS AND SEQUELAE

Febrile illnesses call for reduction in diet. The amounts of light foods which can be tolerated supply a lower calorific intake than is needed. Deficiency in the vitamins is even more important. Requirements increase with the heightened metabolic rate and several of the vitamins cannot be stored.

Many adolescents and adults bear in their teeth the permanent record of vitamin shortage during past febrile illnesses (*Brit. Dent. J.*, 1940, LXIX, 209). Vitamins A and D, calcium and phosphorus should be supplied daily to all febrile patients. Vitamins B and C are equally necessary.

A multiple vitamin and mineral supplement (Complevite) is an essential addition to restricted diets. It should be begun immediately the restriction begins and continued throughout the course of the illness and in convalescence.

Supplying the full physiological requirements in this way offers the greatest likelihood of shortening the illness and may be the only way of preventing permanent changes in the teeth, such as hypoplasia, with subsequent caries.

100% = The full daily requirement

Average Dietary Deficiency		Complevite supplies, at time of manufacture, approximately	
DEF	DEF	DEF	DEF
1700	VITAMIN A	4000	
150	VITAMIN B	200	
1350	VITAMIN C	1000	
250	VITAMIN D	300	
0.35	CALCIUM	0.35	
0.002	IRON (available)	0.002	
0.12	PHOSPHORUS	0.55	
	TRACE MINERALS		

\*The iron in Complevite exceeds the calculated deficiency expressly to combat the nutritional anemia so common in children and in women of child-bearing age.

## COMPLEVITE

A multiple vitamin and mineral supplement.

## Medical News

## Letters, Notes, and Answers

A meeting of the Middlesex County Medical Society will be held at Hillingdon County Hospital on Saturday, Jan. 8, at 2.30 p.m. when demonstrations of medical and surgical cases, pathological specimens, and new apparatus will be followed by papers by Dr. T. E. D. Beavan on chemotherapy in influenzal meningitis; Dr. C. G. Barnes on hypoglycaemia after partial gastrectomy; and Mr. L. Fatti, interim report on treatment of carcinoma of the lung.

At a meeting of the Pharmaceutical Society of Great Britain, to be held in the Society's house, 17, Bloomsbury Square, London, W.C., on Thursday, Jan. 13, the Hanbury Memorial Medal will be presented to Sir Henry H. Dale, M.D., P.R.S., Director of the Laboratories of the Royal Institution. After the presentation Sir Henry Dale will give an address on "The Natural History and Chemistry of Drugs." The chair will be taken by the President at 7 p.m., and a large attendance of members and friends is hoped for.

At a meeting of the Tuberculosis Association to be held at Manson House, 26, Portland Place, W.1, on Friday, Jan. 21, Mr. J. E. H. Roberts will give his presidential address at 3.15 p.m. on "A Surgical View of Timing." It will be followed by three short papers: "The Local Application of Promanide," by Dr. A. D. App (Toronto); "Some Observations on Tuberculosis of the Lungs and Larynx," by Dr. N. Lloyd Rusby; and "The Examination of Tuberculosis Contacts: A Minimal Scheme," by Dr. Brian Thompson.

A Radiotherapy Section meeting of the Faculty of Radiologists will be held at 32, Welbeck Street, W., on Saturday, Jan. 22, at 9 a.m., when there will be a discussion on "The Indications for and Effects of Irradiation of the Pituitary Gland."

A meeting of the Association of Industrial Medical Officers will be held at 11 a.m. on Saturday, Jan. 22, 1944, at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1. The morning session will be devoted to private business. In the afternoon a discussion will be held on injuries and infections of the hand. Openers: Mr. R. M. Handfield-Jones, F.R.C.S., and Dr. P. H. Jayes.

Series of lectures on the anatomy and physiology of the nervous system, suitable for a Diploma in Psychological Medicine, are being held this month at the Maudsley Hospital, Denmark Hill, S.E.5, on Mondays, Wednesdays, and Fridays, from 2 to 4 or 5 p.m., beginning on Jan. 3. The fee for the course is £3 3s., which is payable at the time of enrolment. Series of lectures on psychology and medical psychology will be arranged to take place during February, and all aspects of psychiatry required for Part II of the D.P.M. examination will be dealt with during the following months. All inquiries should be addressed to Dr. W. W. Kay, acting hon. director of the Maudsley Hospital Medical School, Central Pathological Laboratory, West Park Hospital, Epsom. Telephone No.: Epsom 1408.

The Nutrition Society has arranged two whole-day conferences in London on "Budgetary and Dietary Surveys of Families and Individuals," the first to be held on Saturday, Feb. 5, and the second in the early part of May. At the meeting on Feb. 5 at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C., the chair will be taken by Sir John Orr. The matters for discussion are: (1) methods of budgetary and dietary surveys; (2) organization of large-scale surveys; (3) the statistical validity of methods used in such surveys; (4) relation of expenditure on food to other family expenditure. The speakers will include Mr. A. G. Jones (Ministry of Food), Dr. E. R. Bransby (Ministry of Health), Mr. F. le Gros Clark (Children's Nutrition Council), Prof. M. Greenwood, F.R.S., Dr. A. Bradford Hill, Prof. A. L. Bowley, Mr. D. Caradog Jones, and Dr. E. H. M. Milligan. Further particulars about the meetings and about the Nutrition Society can be had from the hon. secretary, Dr. Leslie J. Harris, Nutrition Laboratory, Milton Road, Cambridge.

The next special film session for doctors and allied personnel will be held at the Odeon Theatre, Broadmead, Bristol, on Sunday morning, Feb. 6, starting at 10.45. Among the films to be shown are "Mass Radiography" and recently completed films on head lice, tuberculosis, and nutrition and mass catering. Admission is free to doctors and qualified medical personnel only. Descriptive programmes may be obtained on application to the Medical Officer of Health, Kenwith Lodge, Westbury Park, Bristol 6. Early application is advised, as the number of seats available will be limited.

The Council of the Royal Medical Foundation of Epsom College will, in March next, award a "France" Pension of at least £30 per annum to a necessitous medical man, fully 55 years of age, who has been registered for five years. Forms of application for this pension may be had from the Secretary's Office, Epsom College, Surrey, and must be completed and returned by the morning of Jan. 31.

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.) Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES—EDITOR, *Ailology Westcent*, London; SECRETARY, *Medisera Westcent*, London. ADVERTISEMENTS, *Articulate Westcent*, London.

B.M.A. SCOTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

## ANY QUESTIONS?

## Angina Pectoris

Q.—*Many I have detailed information about the use of testosterone propionate and nicotinic acid in the treatment of angina pectoris. My questions are: (1) What is the right dosage of either of the two preparations in the treatment of angina? (2) In what cases of angina and for how long are they to be given? (3) What is the theoretical explanation of their use in angina pectoris?*

A.—The action of nicotinic acid in angina pectoris probably depends upon its vasodilating property. There is no standard dose, the correct one being the amount which produces the desired effect without producing unbearable flushing. Up to a gramme in many divided doses has been given. The action of testosterone propionate is probably similar, though other factors may possibly be involved. Hypogonadal patients treated with androgens usually experience an increased sense of well-being, and this fact may contribute to the good results reported. Angina is often a symptom of hypothyroidism, and testosterone raises the basal metabolic rate. In rats, male hormones increase the size and functional efficiency of the heart muscle fibres. Nevertheless it seems likely that the vasodilator effect of androgens is the important factor in the treatment of angina. The dose usually employed is 50 to 100 mg. a week of testosterone propionate intramuscularly. If good results are obtained, a maintenance dose of methyl testosterone may be given, the dose being four times the effective dose of the propionate. The tablets of methyl testosterone are put between the upper lip and the gum and allowed to dissolve slowly. Whether nicotinic acid or methyl testosterone is used, it is necessary to continue treatment indefinitely. Though good results have been reported by many observers, especially with androgenic treatment, I must confess that I have not been greatly impressed by my own experience.

## Delayed Menarche

Q.—*As medical officer to two large boarding schools for girls I am convinced there has been a large increase in the number of girls reaching the age of 16 without having ever menstruated. This has been noted during the last two years. What is the reason, and what is the most satisfactory treatment?*

A.—In matters of this kind it is misleading to draw conclusions from general clinical impressions, or even from careful notes which deal with a comparatively small number of cases. Many observers have done so in the past, and this explains the many varying statements in medical literature regarding the age of the menarche and the factors which affect it. It is commonly stated that the average age for the onset of menstruation in Great Britain is about 14 years and the upper limit of normal is 16. Yet W. P. Kennedy (*J. Obstet. Gynaec. Brit. Emp.*, 1933, 40, 792), in a review of 10,219 women of hospital class, found that 2,688 did not menstruate until they were 16 or over. The mean was  $15.037 \pm 0.011$ , with a standard deviation of 1.707. The inquirer should refer to this paper, in which he will find comparable figures published in Russia, Prussia, and Italy—each showing similar results.

There is general agreement that race, extreme climatic conditions, environment, social status, etc., can affect the age of the menarche. Thus, delayed puberty or amenorrhoea is said to occur more frequently in girls subjected to an "institutional life"—e.g., girls in boarding school and nurses during hospital training. But judging by the contrary statements as to the exact effect exerted by factors of this kind, it seems clear that most have been made on evidence which would not satisfy present-day scientific standards.

In view of considerations of this kind, the assumption in the question cannot be accepted without further data. Until it is proved it is pointless to enlarge on possible explanations, though it would be easy to postulate change in diet, the war and its attendant anxieties and strains, altered facilities for recreation, etc. It should

be remembered that it is common under any circumstances for menstruation to be delayed beyond the 16th birthday, and such delay does not necessarily imply any abnormality. The premature employment of any form of hormone therapy should therefore be avoided as needless and possibly harmful. In such cases attention should be paid to the girl's general physical and mental development. If this is normal, then the girl and her parents should be reassured. The only treatment necessary is to ensure that the girl is living a healthy life, not overworking, occupying her leisure hours suitably, and receiving a diet adequate in all respects. If, however, there is other evidence of endocrine disturbance, then complete investigation should be carried out to determine its nature before prescribing any hormone therapy. In a girl otherwise healthy in mind and body, amenorrhoea alone rarely justifies special investigation and treatment until she reaches the age of at least 17, and possibly 18 years.

#### Menopausal Arthritis

**Q.**—About the menopause women are very susceptible to muscular or arthritic pains for which no focal infection can be traced. So common is its incidence that, like flukes, many women attribute it to endocrine dysfunction. Does proof, apart from clinical, support this claim, and what have been the results of oestrogenic treatment?

**A.**—Apart from clinical observations there is little reliable evidence in support of the view that rheumatic disorders at the menopause are due to endocrine dysfunction. Tempelaar and van Breemen carried out observations on 142 women whose rheumatic disturbances were associated with the menopause or with irregularity of the menses, with a preparation of whole ovary and stated that the percentage improvement was lower among the controls than in those receiving ovarian substance (*Acta rheumatol.*, 3, No. 10, 13, 18, 19). F. C. Hall (*New Engl. J. Med.*, 1938, 219, 1015, and *J. Amer. med. Ass.*, 113, 1061) carried out a series of observations on 71 female castrates who developed joint symptoms a few weeks after operation. He gave 10,000 to 20,000 rat units of oestrogenic substance a week for six weeks, and in 40 of the 53 cases in which adequate treatment was given 70% were almost completely relieved of joint and muscular pain. It is suggested that arthralgia and arthritis appear to be phases of the same process due to excess of anterior pituitary hormone in the absence of ovarian hormone. Hench (*J. Amer. med. Ass.*, 113, 1062) found oestrone disappointing and Cecil had similar results. Monroe (*Chronic Arthritis*, Oxford Loose Leaf Medicine, London, 1939) states dogmatically that none of the ductless glands plays a part in originating any type of arthritis.

It is a striking feature from the clinical aspect that rheumatic symptoms develop far more often after the artificially induced menopause than in the natural course of events. In my opinion the probable explanation is that normally, as the supply of ovarian hormone falls, the thyroid takes over its functions in metabolism under the balancing influence of the pituitary. Should the supply of thyroid hormone be inadequate symptoms arise due to this, notably the development of a chronic villous synovitis of the knees and of dense fibrositic deposits in various parts, especially on the inner aspect of the knees and across the back of the neck, together with a slight lowering of the basal metabolism and a raised blood sugar. The factor determining the site of the rheumatic manifestations is mild trauma from overstrain, such as results from flat-foot and other deformities of the feet; frequently also there is a tendency to overweight. In favourable cases the thyroid will gradually overcome the deficiency; but where, as in the artificially induced menopause, the deficiency arises abruptly, symptoms appear more acutely. The use of oestrogenic substances is merely a substitution therapy and should be graduated accordingly so as to give the thyroid time to "catch up." Thyroid itself is generally more satisfactory except for the relief of more urgent developments, and in small doses in conjunction with iodine given over a long period is the most useful line of treatment. Reduction of strain by attention to foot deformities and the like, and by dieting to control any tendency to put on weight, are important adjuncts to the treatment.

#### Myxoedema and Pregnancy

**Q.**—A patient aged 34, mother of two children now aged 5 and 3, developed myxoedema a year ago. This responded to treatment, and she is now perfectly well on a maintenance dose of 2 gr. thyroid (dry ext.) daily. She has now become pregnant. (1) Is there any danger of cretinism in the baby? (2) Is modification of the dose of thyroid during pregnancy or afterwards likely to be necessary?

**A.**—There is no danger of cretinism in the baby, and it is unlikely that the dose of thyroid for the mother will require appreciable modification during or after pregnancy. A cretin baby may be produced when there is endemic goitre, but not because a mother is suffering from spontaneous myxoedema. In fact Parkin and Greene (*J. clin. Endocrinol.*, Aug., 1943) have recently recorded cases of juvenile and adult myxoedema on which pregnancy has supervened

although they were quite untreated before pregnancy, and in which the baby was completely normal, though no treatment with thyroid was given during pregnancy. Incidentally it is rare for pregnancy to occur in a woman with untreated myxoedema.

#### Intractable Acne

**Q.**—I would be grateful for advice on a persistent case of acne vulgaris and pustularis in a youth of 16. He is dark-haired with a greasy skin. The eruption is present on his back, forehead, chest, and nuchal areas. There is much scarring from old pustules, but I am more concerned at the continual outbreak of pustules. He is on an antiseborrhoeic diet, free of fried food, grease- and fat-free, and no sweets. I insist on daily baths with medisoap No. 67, and I have given him erythematous doses of local ultra-violet light. He is also using a zinc sulph., potass. sulphurata, and acetone lotion, and I am now giving an autogenous *Staph. aureus* vaccine. A radiologist is giving him superficial x rays once weekly. Is hormone or stock acne bacillus vaccine of any value?

**A.**—Acne vulgaris is a chronic and rebellious disorder; it may be assumed that the youth of 16 will continue to be affected for months or years. The record of the treatment already given follows the recognized lines and can be continued. As x-ray treatment must be strictly limited, later the U.V.R. can be resumed. Although various hormonal substances have been used for acne, the results have not been encouraging, and this also applies to acne bacillus vaccine. Massage with a Bier's cup is occasionally of value.

#### Lint: Which Side?

**Q.**—Which side of the lint should be placed next to the wound? I have always used the smooth side, but several times lately I have heard it stated that the fluffy side is specially prepared to have a "velvety" softness, and therefore should be placed next to the skin. This is perhaps too small a matter for publication under "Any Questions?"

**A.**—When lint—i.e., fluffed linen, both words being derived from *linet*—flax) was first introduced its use was chiefly as an external application—often with added medication—to the unbroken skin. For this purpose the soft fluffy side is ideal from the comfort point of view, and it also holds plenty of the medicament—e.g., Scott's dressing. When used on a raw surface the smooth side (non-fluffed) is the better one to apply to the wound, but it is probable that other materials—gauze, etc.—are best for this purpose.

#### INCOME TAX

##### Commencement of Practice

L. G. commenced a practice in March, 1943, in succession to a deceased practitioner. He has already been assessed for the year 1943-4 and the inspector of taxes informs him that he will be liable to account for the first instalment of the tax in January, 1944.

The inspector is acting legally, but L. G. is entitled, of course to give notice of objection to the assessment, pointing out that the correct liability cannot be calculated until after his accounts to the end of March, 1944, are made up. In the meantime he is entitled to decline to pay on any amount in excess of the probable (or undisputed) liability, and if necessary the Commissioner of Taxes can be asked to decide what amount he should pay. Whether the inspector would be prepared to put all parties concerned to the trouble of such proceedings in order to ensure that tax is paid in, say, February instead of, say, May is doubtful.

#### LETTERS, NOTES, ETC.

##### A Rare Presentation

Dr. LEONARD LEY (Great Yarmouth) writes: The following note of a rare condition may warrant publication. I was called in by the midwife because of delay in delivery of a second twin (the first, a girl, had been born 4 hours with a tear of the perineum). When I arrived pains were strong. Presentation with head well down was vertex anterior. I gave pituitrin. The head was delivered and I freed the chin. I then saw first one hand and then the other present alongside the face. I eased the arms out and then delivered the foetus to the upper end of the sternum. As this level of the trunk appeared toes and a foot (the left) presented and lay under the chin. I have dealt with some 2,000 confinements and have mentioned this case to two colleagues who have probably done 2 many or more, and none of us has seen or heard of such a happening. This child was a male.

##### Corrigendum

Prof. GEOFFREY JEFFERSON wishes to point out that the top two illustrations at page 3 of his paper on "The Nature of Concussion" in our issue for Jan. 1 refer to Case 2 and Case 1 respectively. The lower one illustrates Case 3.

## CLINICAL FEATURES AND TREATMENT OF MALARIA IN BRITISH TROOPS IN WEST AFRICA

BY

S. B. HUGHES, M.D.

Capt. R.A.M.C.: Graded Physician

AND

R. R. BOMFORD, D.M., F.R.C.P.

Lieut.-Col. R.A.M.C.: Officer in Charge of a Medical Division at a Military Hospital;  
Assistant Physician to the London Hospital

"The symptoms of this fever, it is to be regretted, are so various and irregular, in different cases and under different circumstances, that a mere nosological definition of them would afford no precise information and might mislead those it was intended to instruct." Since Boyle in 1831 wrote these words in his gloomy *Account of the Fevers of Western Africa* the prognosis of subtertian malaria has greatly altered, but the diversity of its manifestations has not. Modern textbooks may claim to provide more than a mere nosological definition, but they tend to emphasize the severer and rarer types of the disease to the exclusion of its commoner and milder, though no less protean, forms. As the latter are prevalent in troops in West Africa at the present time and are not uncommon in those returning to this country, we believe that a fresh description of them may be of value. Pernicious types will receive little notice, as in our experience they occurred infrequently, and methods of investigation requiring more than the simple use of the microscope will hardly be mentioned.

The description is based on over 1,200 cases seen and treated by one or both of us in two military hospitals in West Africa in 1941 and 1942. Where figures are given these refer to 846 unselected cases in 584 patients from one hospital in each of which the diagnosis was confirmed by the finding of malaria parasites in the blood. In 380 cases the parasites were diagnosed as *Plasmodium falciparum*. In the remainder no diagnosis of the type of parasite was attempted, but it can be assumed for the purpose of this paper that all or nearly all were due to *Pl. falciparum*, since in no instance did the appearance of the parasite or the clinical features of the disease suggest the contrary, and workers in the district concerned agree that other types of malaria are rare, occurring, when they do, usually in visitors who have been infected elsewhere.

Our account deals with a group of white males aged 18 to 51 who had been passed as fit for overseas service, who were in most cases in a malarious district for the first time, and amongst whom the observance of antimalarial precautions and the taking of a suppressive drug were enforced, so far as they could be, by disciplinary measures. Further, in British West Africa subtertian malaria is for the most part hyperendemic and, on account of the climate and the varying habits of the principal anopheline vectors (*A. gambiae*, *A. gambiae* var. *melas*, and *A. funestus*), infections, though commonest in the wet season, occur all the year round. Conclusions based on the study of a particular type of patient in an area with particular characteristics are not necessarily applicable to other types of patient in other areas.

### Previous Descriptions

We know of no previous account of the clinical features of malaria in white troops in West Africa. Small groups or single cases of the disease, acquired in West Africa but treated in England, have been described by Fawcitt (1940), Fawcitt and Walters (1941), Murray and Shute (1942), and Anderson and Bradshaw (1943); and treatment has been discussed by Hughes (1942), Hill (1942a, 1942b), and Hughes and Murgatroyd (1943).

### The Clinical Types of Malaria

Malaria has been described as the great mimic of other diseases. To illustrate this fact, which is of great importance in diagnosis, we have divided our cases into clinical types, according to the principal feature of the attack, much in the same way as did Falconer and Anderson (1917) and Manson-Bahr (1920) in their respective descriptions of malaria in the Salonika and Egyptian Expeditionary Forces of the last war. While the exact pathogenesis of these types can only be a matter for speculation, it was noticeable that patients who had repeated attacks showed no predilection for a particular type of the disease.

The "types" described below accounted for 818 of our 846 cases. The remainder consisted of 24 particularly mild cases in which the patients had no fever and complained only of headache and slight malaise, and 4 cases with jaundice as the principal feature, which will be mentioned under the heading "Complications."

#### 1. The Febrile Type

In this type (684 cases) fever itself was the main feature. The onset was usually quite sudden, with chilly feelings or shivering, soon followed by feverishness. During the hot stage, which lasted from 10 to 36 hours, the temperature was raised to 103 or 105°, and the patient complained of burning heat and great discomfort or was quite prostrated. In most cases this stage ended with profuse perspiration, a fall in temperature, and a sense of great relief, to be succeeded by an apyrexial interval, whose length was from a few to 36 hours and which often varied inversely with that of the preceding hot stage. While afebrile the patient felt quite well or complained only of slight headache. In some cases there was no apyrexial interval, and symptoms continued till the fever was controlled by an antimalarial drug.

During the febrile stage headache, backache, and generalized aches and pains were usually present. Pain in the back of the neck and aching across the shoulders, associated sometimes with stiffness in these regions, were common complaints, as were also aching in the eyeballs and pain behind the eyes, aggravated by moving them. Vomiting occurred in about a third of these cases in the febrile stage, and in some instances was very distressing, being accompanied by much retching. Some patients complained of abdominal pain, either diffuse or localized in the left hypochondrium or epigastrium, and others of pains in the chest which suggested intercostal myalgia or pleurisy or were of an indefinite nature. In some of the cases included in this type the symptoms were milder, and the patients had often remained at duty for several days before reporting sick.

Rigors occurred on only 22 occasions, and are therefore rare in malaria of this type. Their occurrence should suggest the possibility of the onset of blackwater fever and call for the keeping of a close watch on the patient and his urine.

## II. The Gastro-intestinal Type

Gastric, diarrhoeic, and dysenteric forms were recognized.

(a) *Gastric*.—Vomiting was the principal feature in the 11 cases of this type. Epigastric discomfort, at times amounting to actual pain, and constipation were usual, and headache and backache were complained of on occasion. The fever was mild in all instances, and the vomiting differed from that which occurred in the febrile stage of cases of the previous type in that, though more persistent, it was less distressing and was not associated with retching. The symptoms were continuous or irregularly intermittent, except in one case in which they recurred on alternate days. Some of these patients were sent to hospital with a diagnosis of "dyspepsia" or "acute gastritis." In all instances the symptoms cleared up rapidly when antimalarial treatment was instituted.

*Illustrative Case*.—Sgt. T. was admitted to hospital with a history that four nights previously he had complained of nausea and vomiting, and these symptoms had continued all the next day. Two days before admission he had been free from symptoms and felt well till the evening, when nausea and vomiting returned. The symptoms had continued all the next day, and were associated with epigastric discomfort and complete anorexia. On the day of admission he felt better but weak. No malaria parasites were found in films of his blood. That night he complained again of epigastric discomfort, vomited repeatedly, and his temperature rose to 100.4°. On the following day his spleen was palpable, malaria parasites were present in blood films, and quinine bisulphate gr. 10 t.d.s. was prescribed. He made a rapid and uninterrupted recovery.

(b) *Diarrhoeic*.—The principal feature in the 60 cases of this type was simple diarrhoea, accompanied in most instances by colicky abdominal pain of varying severity. In a third of the cases this began suddenly, and was associated with headache of mild severity and vomiting of short duration. In the remainder diarrhoea, mild colicky abdominal pains, and a feeling of malaise had been noticed for several days before the patient felt ill enough to report sick. These patients had few symptoms apart from their intestinal ones, and were sometimes sent to hospital merely for the investigation of a diarrhoea which had failed to respond to the usual remedies. None had high fever and 11 of them had no fever while in hospital. The stools were watery, did not contain blood or mucus, and varied from 5 to 18 or more in the 24 hours. In the majority of cases the diarrhoea was continuous, but in some it occurred on alternate days. The stools were examined microscopically in every case; in the majority nothing abnormal was detected, but in about a quarter of them pus and red blood cells were present. They were cultured on a number of occasions, but no organisms of pathogenic significance were isolated.

*Illustrative Case*.—Pte. B. was admitted to hospital with a history of diarrhoea and colicky abdominal pain for six days. His motions had been watery and had numbered between seven and ten daily. He had never noticed blood or mucus, and did not complain of other symptoms. His temperature was 100.6°, pulse 74, and respirations 20. He had mild angular conjunctivitis, the lower edge of the liver was palpable and tender, but no other abnormal signs were present. During the first two days in hospital no malaria parasites were found in blood films; microscopical examination of the stools showed some pus and red blood cells only, and culture of them revealed no abnormality. On the third day malaria parasites were found and treatment with quinine was begun. The temperature became normal in 48 hours and the diarrhoea disappeared on the third day of treatment.

(c) *Dysenteric*.—In 12 cases of this type diarrhoea, with blood and mucus in the stools, was the main feature, and was accompanied by headache, fever of moderate severity, and abdominal pain. The onset was almost always sudden; the fever and constitutional disturbance were greater than in cases of the previous type and the diarrhoea was more profuse and distressing, as many as 30 motions being passed in 24 hours. Backache was complained of in a few cases; vomiting was unusual, and tenesmus quite exceptional. The stools were cultured repeatedly, but no pathogenic organisms were discovered.

*Illustrative Case*.—Sgt. G. was admitted to hospital with a history of diarrhoea, with blood and mucus in the stools, 25 having been passed in the previous 24 hours. He had complained of headache on the evening before admission and stated that he had had a temperature of 102° at the same time. On admission his temperature was normal and his tongue slightly furred; no other abnormality was discovered on physical examination, and no malaria parasites were

found in blood films. The stools contained pus and red cells, but no pathogenic organisms were grown on culture. On the following day his condition was unaltered until the evening, when he complained again of headache and generalized aching and his temperature rose to 101°. On the third day his temperature was normal, but bloody diarrhoea continued and films were still negative for malaria parasites. On the fourth day malaria parasites were found in blood films, and quinine bisulphate gr. 10 was administered thrice daily. Three days later his bowels acted normally and thereafter he made an uninterrupted recovery.

We saw no case of malaria of an appendicular type in West Africa. We did, however, see one of true appendicitis in a patient with malaria. Since returning to this country one of us has seen a typical case of malaria simulating acute appendicitis. The presence of a leucopenia was the main differentiating feature, and the condition cleared up rapidly when treatment with quinine was started.

## III. The Respiratory Type

In 39 cases the main clinical feature was an acute or subacute bronchitis, patients with a previous history of chronic or recurrent bronchitis being excluded from this group. The symptoms varied from the acute respiratory distress of an asthmatic attack to a moderate degree of cough and expectoration. Some fever was the rule, but in a few instances it was insignificant in degree or absent. The attack usually began abruptly with headache, backache, and generalized aching. After a variable period respiratory symptoms appeared. The cough, at first dry and unproductive, soon became looser, but expectoration was seldom profuse. Wheezing and vomiting occurred in some instances. Rales and rhonchi were heard on physical examination, and in a few cases the clinical picture suggested the presence of a bronchopneumonia; but radiographs of the chest did not confirm these clinical findings.

*Illustrative Case*.—S/Sgt. P. was admitted to a hospital with a history of a few hours' feverishness, headache, generalized aching, and vomiting. His temperature was 102°, pulse 88, and respirations 24. He was wheezing and had considerable respiratory distress. On examination of the chest numerous sibilant rhonchi were heard in all areas. Malaria parasites were present in a blood film, and quinine bisulphate gr. 10 t.d.s. was prescribed. Seven hours later he had a profuse perspiration, but wheezing continued and he was given a hypodermic injection of adrenaline with good effect. He was better next morning, with only slight wheezing, and expectorated abundant frothy sputum, but the same evening his acute symptoms returned. On the following day the sputum became mucopurulent and the spleen was palpable, but the symptoms abated. On discharge 12 days after admission he complained of slight cough only and the spleen was no longer palpable.

## IV. The Myalgic Type

In 10 cases the main feature was muscular pain and stiffness. In six of them there was no fever and in three no more than slight fever. The onset was usually acute, with pain localized to the affected muscle or muscles, and constitutional symptoms were slight or absent. On examination the affected muscles were tender and in spasm, and active or passive movement caused acute pain. The muscles most often affected were the lumbar, the intercostal, and those of the neck, either singly or in combination. Rest, salicylates, and heat provided temporary relief; but only when malaria parasites were demonstrated in the blood and the appropriate treatment was administered did complete recovery ensue.

*Illustrative Case*.—Sgt. T. was admitted to hospital complaining of pain and stiffness of the right side of the neck that had come or suddenly two days previously. There was tenderness and spasm of the right sterno-mastoid and of the cervical portion of the right trapezius, and the condition differed in no way from an ordinary acute torticollis. No other abnormal physical signs were noted, and a blood film revealed no malaria parasites. Salicylates by mouth and radiant heat and massage were prescribed without beneficial effect. Two days later, as no improvement had taken place, further blood films were examined: malaria parasites were demonstrated and quinine bisulphate gr. 10 t.d.s. was administered. The pain was much improved in 48 hours and the condition cleared up completely in five days. The patient had no other symptoms and was afebrile throughout.

## V. The Cerebral Type

The 2 patients in this series had cerebral symptoms. The first was conscious, but was completely disorientated, had some motor aphasia, and was afflicted with severe muscular

itchings. The second was delirious and gravely ill, with dry brown tongue, a paralytic squint, and a left extensor plantar response. Both recovered completely.

### General Features

The following features applied to some extent to all types of cases.

**Onset.**—This was sudden in the majority of cases, but in minority (152) was preceded by a prodromal period, lasting on a few days to a few weeks of malaise, headache, asthude, backache, or diarrhoea.

**Symptoms.**—The main symptoms of the attack, irrespective of type and in order of frequency, were headache (770), backache (486), shivering (253), vomiting (234), feverishness (233), in the back of the neck (184), generalized aching (180), ght cough (169), sweating (153), and simple diarrhoea (134). Constipation (61) was the exception.

**Temperature.**—Quotidian intermittent fever was seen in 45 cases; tertian intermittent in 49; subtertian intermittent in 53; regularly intermittent in 87; remittent in 75; continuous in 1; "low fever" (pyrexia not exceeding 100°) in 91; and no fever throughout in 50. In 366 cases the fever did not last long enough to be of any special type.

**Pulse Rate.**—Relative bradycardia was a principal feature of the disease as seen by us in West Africa. An analysis of the pulse-temperature ratio is as follows:

Temperature	Corresponding Average Pulse Rate per Minute	No. of Observations made
106°	102.0	59
104°	87.2	177
103°	91.6	177
102°	86.5	177
101°	83.9	177
100°	79.2	177

**Urine.**—Albuminuria, varying from the presence of a trace to a heavy deposit in the boiled specimen, was reported on occasions, and reduction of Fehling's solution in 17 cases. Others were transient features.

### Physical Signs

The spleen was palpable on admission in 315 cases, at some time during the acute attack in 462 cases, and on discharge approximately two weeks after admission in 137. Tenderness of the splenic region was noted in 114 cases. The liver was normally palpable in 32 cases, the greatest degree of enlargement being to three inches below the costal margin; and tenderness of the liver on palpation was noted in 61. Diffuse dominal tenderness was noted in 19 cases and slight dominal rigidity in 7. The tongue was usually moist and an, and was never more than slightly furred in uncomplicated cases. Angular conjunctivitis in some degree was not common, and a faint icterus of the conjunctivae without noticeable involvement of the skin was seen occasionally. Ronchi were heard in the chest in 136 cases, sometimes accompanied by rales.

### Complications

**Chronic Malaria.**—Out of 584 patients 6 were considered, or several acute attacks, to be suffering from chronic malaria. Such patients usually complained of chronic headache, fatigue, and general ill-health. They looked sallow, and some degree of splenomegaly—the spleen being harder in consistency than that commonly felt in acute attacks—an aemia of slight to moderate degree with leucopenia and a relative lymphocytosis, and had often lost weight. In many instances of so-called "chronic malaria" the objective signs are slight, the symptoms appeared to be mainly emotional, and simple psychotherapy was more needed than drugs.

**Blackwater Fever.**—Four patients out of 584 developed this complication, and two of them died.

**Jaundice.**—Definite jaundice was seen in 11 cases and slight icterus of the conjunctivae in 14. Three types of jaundice were recognized: (i) The acute haemolytic jaundice of blackwater fever. (ii) Slight icterus of the conjunctivae only, which was present during the acute attack and was presumably due to haemolysis. (iii) Jaundice, usually of moderate severity, with clay-coloured stools and dark urine, indistinguishable

clinically from catarrhal jaundice or infective hepatitis. In four cases this was present on admission, and in two it appeared during treatment with mepacrine. As in at least two cases, not included in this series, similar jaundice appeared during treatment with quinine, it is unlikely that mepacrine was responsible for it.

**Herpes Inibialis** occurred in 41 cases and herpes nasalis in 5.

**Generalized urticaria** occurred in 3 cases—in two during treatment and in one at the onset of the attack.

### Severity and Prognosis

In less than 10% of these cases could the patient be described as severely ill and in less than 1% as dangerously ill. Of those described as severely ill the majority were simply patients who responded unusually slowly to treatment, and these probably corresponded to the 12% of patients shown by Howie and Murray-Lyon (1943) to absorb or metabolize abnormally quinine given by mouth, as disclosed by the irregular occurrence or absence of positive Tanret reactions in the urine. Out of 584 patients 14 (2.4%) were invalided home, the indications being chronic malaria (7), recovery from cerebral malaria (2), recovery from blackwater fever (2), anaemia (1), persistent jaundice (1), and haemolytic jaundice of uncertain origin (1). There were no deaths from uncomplicated malaria. Two patients out of 584 died from blackwater fever—a mortality rate for the whole series of 0.34%.

We believe our account to show that, given favourable conditions, malaria in West Africa at the present time need not enjoy the evil reputation that it has. The disease is potentially a very dangerous one, and its apparent mildness may occasionally prove its most subtle danger; but unnecessary exaggeration of the dangers of the average case causes needless alarm and contributes to disability from "tropical neurasthenia."

### Diagnosis

Films were usually taken at 12- to 24-hourly intervals, and in 968 cases parasites were found at the first examination in 57%, at the second in 22%, at the third in 5%, at the fourth in 3%, and at the fifth and sixth in under 1% (an "examination" for this purpose meaning the search of a thick film for not less than 10 minutes); while in 13% parasites were not found and the condition was treated as "clinical malaria."

When the clinical findings are equivocal it is wise to examine repeated blood films, but the above figures show that parasites will usually be found, if they are going to be, in the first two or three examinations. With us the apyrexial interval was as favourable as any other time for the finding of parasites, for out of 816 positive films 389 were taken when the patients were afebrile.

While films are being taken for the diagnosis of equivocal cases in hospital the administration of a suppressive drug should be discontinued, as the parasites are then more likely to be found. We have never seen any harm come of this practice. Patients in hospital for any other purpose should continue to take their suppressive drug, and patients undergoing surgical operations should be given 10 gr. of quinine or 0.1 g. of mepacrine daily. If this is not done an attack of malaria two or three days after the operation is not uncommon, and at best adds considerably to the patient's discomfort.

### Treatment

In a district of the type described here it is likely that most residents become and remain infected with malaria. Many of them must be regarded as living in a state in which the forces of infection and of resistance are in a somewhat precarious balance, and a clinical attack may result from anything which serves even temporarily to reduce the powers of resistance—such, for instance, as a surgical operation, an intercurrent infection, or an interruption of suppressive treatment. Since there is at present no known drug treatment that will terminate human infections and there is reason to believe that immunological processes play a considerable part in their control (Coggeshall, 1943), the objects of treatment in such an area must be to aid natural resistance to the disease and by the use of drugs to suppress or abort clinical attacks.

While little is known of the nature of the immunological processes involved, it is reasonable to suppose that they will be aided by the maintenance of a high standard of general health, and in practice measures to this end do appear to be important. In our experience ambulant patients or those treated in their own quarters did not regain a feeling of well-being as quickly as those kept in hospital for an adequate period, and they had a greater tendency to early relapse, though the same course of drugs may have been administered in each case. We had an impression that the same applied to patients receiving an unnecessarily large dosage of drugs. Whatever drugs are given patients should, except in an emergency, be treated in hospital and should remain there for a minimum of 12 to 14 days. It is false economy to treat patients otherwise or to cut short their convalescence.

We believe that this principle could be carried further and that the provision of convalescent camps in West African stations is a measure which would save its own cost by reducing disability from malaria. Such camps should be situated in relatively healthy areas, preferably with facilities for bathing and other recreation; and convalescence in them should be planned, and should include graded exertion so that return to normal duty does not involve a sudden unaccustomed strain. *The Medical History of the War, 1914-18*, describes the provision of such camps as "a practice which obtained recognition during the war," and states that convalescence should last at least three weeks.

#### Treatment of the Acute Attack

In the height of the fever patients were nursed in blankets. Warm sponging, drying, and changes of clothing as often as necessary added considerably to their comfort. The disadvantage of sedatives is that they usually produce profuse sweating without relief of symptoms. We began by treating all our patients with a full course of quinine, mepacrine, and pamaquin, under the assumption that the more "thorough" the treatment the less likely was the occurrence of relapses. This assumption was not justified, for we found that our return cases were no less numerous than anyone else's. We next tried treating the patients in one ward with quinine followed by pamaquin, and those in another with mepacrine followed by pamaquin. We found that patients in the quinine-pamaquin ward became apyrexial and free of symptoms quicker than those in the mepacrine-pamaquin ward, but thought that return cases were less common in the mepacrine-pamaquin ward than in the quinine-pamaquin one. We next abandoned pamaquin for routine use because:

- (i) It is doubtful whether pamaquin has any anti-relapse value in malignant tertian malaria (Sinton and Bird, 1928).
- (ii) The destruction of gametocytes, which pamaquin does achieve, is of little importance in Europeans in a hyperendemic area where there is a huge reservoir of infection in the native population.
- (iii) Cyanosis and abdominal colic occurred in a few of our patients under treatment with pamaquin.
- (iv) Haemoglobinuria had been reported in patients under treatment with pamaquin (Sinton, Smith, and Pottinger, 1930; Mann and Smith, 1943), and we heard of a few recent cases of blackwater fever during administration of this drug.
- (v) We were unable, as was not the case with quinine and mepacrine, to demonstrate to ourselves that in the treatment of our patients pamaquin had any value other than the destruction of gametocytes.

After abandoning the use of pamaquin we settled on a routine course of quinine by mouth for two days (sometimes extended to three if the fever had not fallen to below 100° at the end of 48 hours), followed by mepacrine for six days. This modification produced no evident deterioration in our results; patients who had been treated by the earlier methods stated that they felt better after the modified course, and the proportion of cases returning within three months was distinctly less after this treatment than after the previous ones. Quinine was given as a solution of such salts as were available, in doses of 10 gr. t.i.d. if necessary in an acid mixture. Mepacrine was given in doses of 0.1 g. t.i.d. If vomiting occurred we substituted for the usual quinine mixture quinine bishydrochloride in tablet form, and found that this could be taken in most cases.

We used quinine by injection in all cases considered to be suffering from pernicious forms of the disease, in a few cases in which even tablets of quinine bishydrochloride were vomited, and in very occasional and quite exceptional cases (less than 1%) which did not appear to be responding to quinine by mouth. The routine use of quinine injections, as recommended for instance by Wingfield (1943), even granted that a high proportion of severe cases may be seen in England, seems to us excessive and unnecessary.

As our patients were kept in hospital for 12 to 14 days in any case we did not give quinine and mepacrine simultaneously; but there is no objection to this practice, and mepacrine acts slowly it may with advantage be begun 24 hours before quinine is discontinued. If mepacrine alone is used the initial doses should be greater than 0.1 g., but the optimum dosage for this purpose remains to be determined. We have recently used an initial dose of 0.8 g. followed by 0.1 g. t.i.d. in a few cases in England with good results.

As soon as the course of treatment was completed our patients returned to their usual suppressive dose of quinine or mepacrine.

#### Treatment of Pernicious Attacks

These must always be regarded as medical emergencies, and should be treated promptly and, in the initial stages, by injection. We do not propose to enter into the controversy as to the best route for the injection of quinine. We use both intravenous and intramuscular injections on occasion without encountering ill effect. In a patient who is conscious and can take quinine by mouth and absorb it (as shown by the Tanret test in the urine) nothing was gained, in our experience, by giving more than two or at most three parenteral injections. In comatose patients or those unable to take or absorb drugs given by mouth, parenteral injections must be continued till the symptoms are controlled. Intravenous glucose and saline may be necessary to prevent dehydration. In a few cases we tried reconstituted plasma as suggested by Fawcett and considered the results promising. In patients with cerebral malaria who failed to respond to other measures therapeutic lumbar puncture seemed to be of value.

#### Suppressive Treatment between Attacks

The taking of a small dose of so-called "prophylactic" quinine has been customary among Europeans on the West Coast for at least a century, and is strongly recommended by most local practitioners of experience. This measure is undoubtedly of some value, and is considered essential for troops under active-service conditions. In practice the results are not quite according to theory, and a varying degree of individual susceptibility appears to be of importance; for some individuals can go for long periods with no suppressive drugs and have little or no malaria, while others have repeated attacks in spite of them.

In dealing with troops under active-service conditions exertions cannot be made, and the taking of a suppressive drug on parade and under the supervision of an officer is enforced. It is likely that mepacrine will replace quinine for this purpose in troops in West Africa, and according to Hill (1942a, 1942b) doses of 0.1 g. daily can be taken with good effect and without the appearance of toxic manifestations. It is important that persons leaving malarious districts of this type should be instructed either to continue with their normal dose of suppressive drug for at least two months after they have left the area or to continue this dose for two weeks and then take mepacrine 0.1 g. thrice daily for five or six days.

#### Summary

846 unselected cases of malaria in British troops in West Africa, every one confirmed by the finding of parasites and presumably almost all subtertian in type, were divided according to the principal clinical feature of the attack into febrile, gastric, diarrhoeal, dysenteric, respiratory, myalgic, and cerebral types.

While its apparent mildness may occasionally prove the most subtle danger, under the conditions stated, which include compulsory personal antimalarial precautions and taking of suppressive drugs, the prognosis in ordinary cases was excellent, and pernicious attacks and complications were very rare. Only 14 patients died, both from blackwater fever, and 14 were invalided home.

After various modifications in treatment the routine use of pamaquin was abandoned. The most generally useful course of drugs in uncomplicated cases was found to be quinine gr. 10 t.d.s. by mouth for two or three days, and mepracine 0.1 g. t.d.s. for six days, the two drugs being with advantage "overlapped" for 24 hours. The patient's usual dose of a suppressive drug was resumed as soon as the course was finished, and an adequate period of convalescence was regarded as of the greatest importance.

Our thanks are due to Col O. J. O'Hanlon, officer commanding a military hospital, for permission to publish this article; to Col. John McFadden and A. McKie Reid for according us facilities for the investigations; to Major I. B. Morris for most of the pathological investigations; to Major J. W. Howe for helpful criticism; and to Dr. A. M. Gillespie, Senior Medical Specialist, Accra, for advice on many occasions.

## DESPECIATED BOVINE SERUM (D.B.S.): A SUBSTITUTE FOR HUMAN PLASMA

BY

F. RONALD EDWARDS, M.D., Ch.M., F.R.C.S.

Assistant to the Professor of Surgery, University of Liverpool

(From the Department of Surgery, University of Liverpool)

The use of plasma in surgical treatment is increasing rapidly, and further studies of the condition of hypoalbuminaemia and its relation to post-traumatic and post-suppurative cachectic states and to delayed wound-healing envisage a still greater demand for plasma protein therapy. The panels of donors and blood banks organized throughout the country have hitherto provided a convenient supply of a protein solution, but the investigation of an alternative source is indicated in view of the future need for this material.

Any plasma substitute must have the following characteristics: (a) it should be retained in the circulation and eventually be metabolized; (b) it should exert an osmotic pressure equivalent to that of plasma; (c) it should be non-toxic, free from antibodies, and non-antigenic. An attempt to produce such a material was made by Bayliss in 1916, when he introduced 6% gum-acacia in saline as a substitute for blood in the treatment of shock (Bayliss, 1917). This material had a very considerable efficiency, but it was only partially metabolized. Much of it remained permanently in the tissues, and many unpleasant sequelae occurred (Hanzlik and Karsner, 1920; Jaylum and Magath, 1932; Yuile and Knutti, 1939; Andersch and Gibson, 1934).

Other organic substances suggested have been isinglass (Taylor and Waters, 1941), pectin (Hartman *et al.*, 1941), gelatin (Gordon *et al.*, 1942), and methyl cellulose (Hueper, Martin, and Thompson, 1942); but they must be absolutely pure, and in the case of the first three this standard is very difficult to obtain. Furthermore, the effective metabolism of such foreign material is very much in doubt. More recently periston (polyvinyl pyrrolidone) has been put forward in Germany (Hecht and Veese, 1943); it has a very high osmotic action, and the claim is made that it will remain in the circulation for two days and be excreted in 3 to 4 weeks. All these substances may have some beneficial effect in maintaining blood volume in shock and haemorrhage, but will have little or no value in restoring loss of blood protein.

The substance most nearly approaching human plasma protein in character, and one which is available in quantity, is animal plasma protein. Unlimited quantities may be obtained in the abattoirs in the form of animal serum. A comparison of the protein constituents of human blood with those of the blood of the animals of which practical use may be made is shown in the following table (Howe, 1925):

	Human	Cow	Horse	Sheep
Total protein, g. %	7.49	7.43	6.10	5.74
Fibrinogen "	0.30	0.72	0.34	0.36
Globulin "	2.73	3.50	2.49	2.31
Albumin "	4.45	3.21	3.27	3.17
Albumin:globulin ratio	62.0:38.0	47.8:52.2	56.6:43.4	57.1:42.9

In total protein, bovine blood most nearly approaches human blood, but there is a much higher percentage of fibrinogen, which, however, is eliminated in the preparation of the serum. Howe's figure for the total protein of bovine blood refers to elderly animals, bullocks usually having a much higher content than this (see below). The albumin:globulin ratio is lower, too, in bovine blood, which might result in a lower osmotic pressure than with human serum, as the albumin fraction, having a smaller molecule, exerts the greater pressure. As bovine serum is obtainable in the largest quantity, however, this material has been utilized in the following investigation.

### Administration of Animal Sera

The infusion of animal sera of full protein content has up to the present been generally unsatisfactory, owing to the high percentage of unfavourable reactions. Kremen and his co-workers (1942) recently gave crude bovine serum an extensive clinical trial in 120 cases, and have declared it unsuitable for general use for the following four reasons: (1) all recipients must be tested by an intradermal dose, positive reactors (approximately 50%) to which do not take the serum well; (2) approximately 60% of the recipients have an immediate reaction after infusion of less than one pint; (3) serum sickness developed in 60% of those cases to which it was possible to administer any quantity of the serum; (4) the rate of administration was so slow as to be practically useless in shock. These authors attempted, furthermore, to absorb the agglutinins on to washed human red cells by mixing these with the serum; but this was only partially successful, and there was a tendency to haemolysis of the human red cells. The incidence of immediate reactions decreased somewhat, but serum sickness was just as prevalent.

### Characteristics of Crude Bovine Serum

Crude bovine serum is orange in colour and of a slightly higher viscosity than human serum. We have found the total protein content to vary between 7.5 and 9.5 g.%, the higher figure being obtained in bullocks (Folin and Ciocalteu's colorimetric method). The values for sugar, chlorides, non-protein nitrogen, and potassium were approximately the same as for human serum. *In vitro* tests showed that when bovine serum was mixed with 50 different samples of human red cells of all groups agglutination occurred rapidly. The titre of this agglutination factor in bovine serum is almost constantly 1/16, and this would not permit of more than 200 c.cm. being administered rapidly with safety to any human being. Furthermore, haemolysis of the human red cells is very definite after a period of one hour. These tests bear out the statement of Kremen *et al.* as to its unsuitability for human administration.

### Removal of the Globulins

As most of the antibodies are known to be attached to the globulins, removal of this fraction might leave a solution of albumin which could safely be given to man. To this end we took samples of bovine serum and precipitated the globulin fraction by half saturation with sodium sulphate. The resulting filtrate was then dialysed in cellophane cylinders against water, leaving behind a solution of albumin. This albumin was passed through a Seitz filter and collected in sterile bottles. A test of the solution showed that there was no agglutination of human red cells. The pH was 7.8.

This albumin solution was administered slowly to two volunteer patients suffering from advanced carcinoma of the

While little is known of the nature of the immunological processes involved, it is reasonable to suppose that they will be aided by the maintenance of a high standard of general health, and in practice measures to this end do appear to be important. In our experience ambulant patients or those treated in their own quarters did not regain a feeling of well-being as quickly as those kept in hospital for an adequate period, and they had a greater tendency to early relapse, though the same course of drugs may have been administered in each case. We had an impression that the same applied to patients receiving an unnecessarily large dosage of drugs. Whatever drugs are given patients should, except in an emergency, be treated in hospital and should remain there for a minimum of 12 to 14 days. It is false economy to treat patients otherwise or to cut short their convalescence.

We believe that this principle could be carried further and that the provision of convalescent camps in West African stations is a measure which would save its own cost by reducing disability from malaria. Such camps should be situated in relatively healthy areas, preferably with facilities for bathing and other recreation; and convalescence in them should be planned, and should include graded exertion so that return to normal duty does not involve a sudden unaccustomed strain. The *Medical History of the War, 1914-18*, describes the provision of such camps as "a practice which obtained recognition during the war," and states that convalescence should last at least three weeks.

#### Treatment of the Acute Attack

In the height of the fever patients were nursed in blankets. Warm sponging, drying, and changes of clothing as often as necessary added considerably to their comfort. The disadvantage of sedatives is that they usually produce profuse sweating without relief of symptoms. We began by treating all our patients with a full course of quinine, mepacrine, and pamaquin, under the assumption that the more "thorough" the treatment the less likely was the occurrence of relapses. This assumption was not justified, for we found that our return cases were no less numerous than anyone else's. We next tried treating the patients in one ward with quinine followed by pamaquin, and those in another with mepacrine followed by pamaquin. We found that patients in the quinine-pamaquin ward became apyrexial and free of symptoms quicker than those in the mepacrine-pamaquin ward, but thought that return cases were less common in the mepacrine-pamaquin ward than in the quinine-pamaquin one. We next abandoned pamaquin for routine use because:

(i) It is doubtful whether pamaquin has any anti-relapse value in malignant tertian malaria (Sinton and Bird, 1928).

(ii) The destruction of gametocytes, which pamaquin does achieve, is of little importance in Europeans in a hyperendemic area where there is a huge reservoir of infection in the native population.

(iii) Cyanosis and abdominal colic occurred in a few of our patients under treatment with pamaquin.

(iv) Haemoglobinuria had been reported in patients under treatment with pamaquin (Sinton, Smith, and Pottinger, 1930; Mann and Smith, 1943), and we heard of a few recent cases of blackwater fever during administration of this drug.

(v) We were unable, as was not the case with quinine and mepacrine, to demonstrate to ourselves that in the treatment of our patients pamaquin had any value other than the destruction of gametocytes.

After abandoning the use of pamaquin we settled on a routine course of quinine by mouth for two days (sometimes extended to three if the fever had not fallen to below 100° at the end of 48 hours), followed by mepacrine for six days. This modification produced no evident deterioration in our results; patients who had been treated by the earlier methods stated that they felt better after the modified course, and the proportion of cases returning within three months was distinctly less after this treatment than after the previous ones. Quinine was given as a solution of such salts as were available, in doses of 10 gr. t.i.d. if necessary in an acid mixture. Mepacrine was given in doses of 0.1 g. t.i.d. If vomiting occurred we substituted for the usual quinine mixture quinine bishydrochloride in tablet form, and found that this could be taken in most cases.

We used quinine by injection in all cases considered to be suffering from pernicious forms of the disease, in a few cases, in which even tablets of quinine bishydrochloride were vomited and in very occasional and quite exceptional cases (less than 1%) which did not appear to be responding to quinine by mouth. The routine use of quinine injections, as suggested for instance by Wingfield (1943), even granted that a higher proportion of severe cases may be seen in England, seems to us excessive and unnecessary.

As our patients were kept in hospital for 12 to 14 days in any case we did not give quinine and mepacrine simultaneously; but there is no objection to this practice, and as mepacrine acts slowly it may with advantage be begun 24 hours before quinine is discontinued. If mepacrine alone is used the initial doses should be greater than 0.1 g., but the optimum dosage for this purpose remains to be determined. We have recently used an initial dose of 0.8 g. followed by 0.1 g. t.i.d. in a few cases in England with good results.

As soon as the course of treatment was completed our patients returned to their usual suppressive dose of quinine or mepacrine.

#### Treatment of Pernicious Attacks

These must always be regarded as medical emergencies, and should be treated promptly and, in the initial stages, by injection. We do not propose to enter into the controversy as to the best route for the injection of quinine. We used both intravenous and intramuscular injections on occasion without encountering ill effect. In a patient who is conscious and can take quinine by mouth and absorb it (as shown by the Tanret test in the urine) nothing was gained, in our experience, by giving more than two or at most three parenteral injections. In comatose patients or those unable to take or absorb drugs given by mouth, parenteral injections must be continued till the symptoms are controlled. Intravenous glucose and saline may be necessary to prevent dehydration. In a few cases we tried reconstituted plasma as suggested by Fawcitt and considered the results promising. In patients with cerebral malaria who failed to respond to other measures therapeutic lumbar puncture seemed to be of value.

#### Suppressive Treatment between Attacks

The taking of a small dose of so-called "prophylactic" quinine has been customary among Europeans on the West Coast for at least a century, and is strongly recommended by most local practitioners of experience. This measure is undoubtedly of some value, and is considered essential for troops under active-service conditions. In practice the results are not quite according to theory, and a varying degree of individual susceptibility appears to be of importance; for some individuals can go for long periods with no suppressive drugs and have little or no malaria, while others have repeated attacks in spite of them.

In dealing with troops under active-service conditions exceptions cannot be made, and the taking of a suppressive drug on parade and under the supervision of an officer is enforced. It is likely that mepacrine will replace quinine for this purpose in troops in West Africa, and according to Hill (1942a, 1942b) doses of 0.1 g. daily can be taken with good effect and without the appearance of toxic manifestations. It is important that persons leaving malarious districts of this type should be instructed either to continue with their normal dose of suppressive drug for at least two months after they have left the area, or to continue this dose for two weeks and then take mepacrine 0.1 g. thrice daily for five or six days.

#### Summary

846 unselected cases of malaria in British troops in West Africa, every one confirmed by the finding of parasites and presumably almost all subtertian in type, were divided according to the principal clinical feature of the attack into febrile, gastric, diarrhoeic, dysenteric, respiratory, myalgic, and cerebral types.

While its apparent mildness may occasionally prove the disease's most subtle danger, under the conditions stated, which included compulsory personal antimalarial precautions and taking of suppressive drugs, the prognosis in ordinary cases was excellent, while pernicious attacks and complications were very rare. Only 2 patients died, both from blackwater fever, and 14 were invalided home.

After various modifications in treatment the routine use of pamaquin was abandoned. The most generally useful course of drugs in uncomplicated cases was found to be quinine gr. 10 i.d.s. by mouth for two or three days, and mepacrine 0.1 g. t.d.s. for six days, the two drugs being with advantage "overlapped" for 24 hours. The patient's usual dose of a suppressive drug was resumed as soon as the course was finished, and an adequate period of convalescence was regarded as of the greatest importance.

Our thanks are due to Col. O. J. O'Hanlon, officer commanding a military hospital, for permission to publish this article; to Col. John McFadden and A. McKie Reid for according us facilities for the investigations; to Major I. B. Morris for most of the pathological investigations; to Major J. W. Howe for helpful criticism; and to Dr. A. M. Gillespie, Senior Medical Specialist, Accra, for advice on many occasions.

## DESPECIATED BOVINE SERUM (D.B.S.): A SUBSTITUTE FOR HUMAN PLASMA

BY

F. RONALD EDWARDS, M.D., Ch.M., F.R.C.S.

Assistant to the Professor of Surgery, University of Liverpool

(From the Department of Surgery, University of Liverpool)

The use of plasma in surgical treatment is increasing rapidly, and further studies of the condition of hypoalbuminaemia and its relation to post-traumatic and post-suppurative cachectic states and to delayed wound-healing envisage a still greater demand for plasma protein therapy. The panels of donors and blood banks organized throughout the country have hitherto provided a convenient supply of a protein solution, but the investigation of an alternative source is indicated in view of the future need for this material.

Any plasma substitute must have the following characteristics: (a) it should be retained in the circulation and eventually be metabolized; (b) it should exert an osmotic pressure equivalent to that of plasma; (c) it should be non-toxic, free from antibodies, and non-antigenic. An attempt to produce such a material was made by Bayliss in 1916, when he introduced 6% gum-acacia in saline as a substitute for blood in the treatment of shock (Bayliss, 1917). This material had a very considerable efficiency, but it was only partially metabolized. Much of it remained permanently in the tissues, and many unpleasant sequelae occurred (Hanzlik and Karsner, 1920; Maytum and Magath, 1932; Yuile and Knutti, 1939; Andersch and Gibson, 1934).

Other organic substances suggested have been isinglass (Taylor and Waters, 1941), pectin (Hartman *et al.*, 1941), gelatin (Gordon *et al.*, 1942), and methyl cellulose (Hueper, Martin, and Thompson, 1942); but they must be absolutely pure, and in the case of the first three this standard is very difficult to obtain. Furthermore, the effective metabolism of such foreign material is very much in doubt. More recently peristom (polyvinyl pyrrolidone) has been put forward in Germany (Hecht and Weese, 1943); it has a very high osmotic action, and the claim is made that it will remain in the circulation for two days and be excreted in 3 to 4 weeks. All these substances may have some beneficial effect in maintaining blood volume in shock and haemorrhage, but will have little or no value in restoring loss of blood protein.

The substance most nearly approaching human plasma protein in character, and one which is available in quantity, is animal plasma protein. Unlimited quantities may be obtained in the abattoirs in the form of animal serum. A comparison of the protein constituents of human blood with those of the blood of the animals of which practical use may be made is shown in the following table (Howe, 1925):

	Human	Cow	Horse	Sheep
Total protein, g. %	7.49	7.43	6.10	5.74
Fibrinogen "	0.30	0.72	0.34	0.36
Globulin "	2.73	3.50	2.49	2.31
Albumin "	4.45	3.21	3.27	3.17
Albumin/globulin ratio	62.0/38.0	47.8/52.2	56.6/43.4	57.1/42.9

In total protein, bovine blood most nearly approaches human blood, but there is a much higher percentage of fibrinogen, which, however, is eliminated in the preparation of the serum. Howe's figure for the total protein of bovine blood refers to elderly animals, bullocks usually having a much higher content than this (see below). The albumin/globulin ratio is lower, too, in bovine blood, which might result in a lower osmotic pressure than with human serum, as the albumin fraction, having a smaller molecule, exerts the greater pressure. As bovine serum is obtainable in the largest quantity, however, this material has been utilized in the following investigation.

### Administration of Animal Sera

The infusion of animal sera of full protein content has up to the present been generally unsatisfactory, owing to the high percentage of unfavourable reactions. Kremen and his co-workers (1942) recently gave crude bovine serum an extensive clinical trial in 120 cases, and have declared it unsuitable for general use for the following four reasons: (1) all recipients must be tested by an intradermal dose, positive reactors (approximately 50%) to which do not take the serum well; (2) approximately 60% of the recipients have an immediate reaction after infusion of less than one pint; (3) serum sickness developed in 60% of those cases to which it was possible to administer any quantity of the serum; (4) the rate of administration was so slow as to be practically useless in shock. These authors attempted, furthermore, to absorb the agglutinins on to washed human red cells by mixing these with the serum; but this was only partially successful, and there was a tendency to haemolysis of the human red cells. The incidence of immediate reactions decreased somewhat, but serum sickness was just as prevalent.

### Characteristics of Crude Bovine Serum

Crude bovine serum is orange in colour and of a slightly higher viscosity than human serum. We have found the total protein content to vary between 7.5 and 9.5 g.%, the higher figure being obtained in bullocks (Folin and Cioclateau's colorimetric method). The values for sugar, chlorides, non-protein nitrogen, and potassium were approximately the same as for human serum. *In vitro* tests showed that when bovine serum was mixed with 50 different samples of human red cells of all groups agglutination occurred rapidly. The titre of this agglutination factor in bovine serum is almost constantly 1/16, and this would not permit of more than 200 c.c.m. being administered rapidly with safety to any human being. Furthermore, haemolysis of the human red cells is very definite after a period of one hour. These tests bear out the statement of Kremen *et al.* as to its unsuitability for human administration.

### Removal of the Globulins

As most of the antibodies are known to be attached to the globulins, removal of this fraction might leave a solution of albumin which could safely be given to man. To this end we took samples of bovine serum and precipitated the globulin fraction by half saturation with sodium sulphate. The resulting filtrate was then dialysed in cellophane cylinders against water, leaving behind a solution of albumin. This albumin was passed through a Seitz filter and collected in sterile bottles. A test of the solution showed that there was no agglutination of human red cells. The pH was 7.8.

This albumin solution was administered slowly to two volunteer patients suffering from advanced carcinoma of the

The solution is easily prepared, is available in enormous quantities, is completely stable, and can be stored at room temperature. It may be administered very rapidly and in large amounts; and no patient seems to have been adversely affected by its introduction.

More detailed haematological and biochemical studies of the effect of its administration in the state of shock, hypoproteinaemia, and protein deprivation and loss are being undertaken, and final judgment must await these results. Despeciated bovine serum would, however, appear to accord with the three precepts given at the beginning as being necessary for a plasma substitute, and as such may have a useful place in the treatment of conditions in which human plasma protein has been of value.

#### Summary

Substitutes for human plasma hitherto prepared have not fulfilled the three criteria: (a) retention in the circulation and eventual metabolism; (b) exertion of an equivalent osmotic pressure; and (c) non-toxicity, non-antigenicity, and freedom from antibodies.

Bovine serum can be made safe for man by destroying the antibodies by heating to 72° C., while rendering the proteins uncoagulable with the addition of 0.2% of formalin and ammonia. Material so prepared appears to accord with the above precepts.

Clinical trial in 26 cases shows that it can be administered rapidly and in large amounts to man with safety.

My grateful thanks for much practical help and advice are due to Prof. O. Herbert Williams, Prof. T. B. Davie, Prof. H. J. Channon, and the late Prof. J. F. Craig. To Prof. T. B. Davie I am also deeply indebted for placing the facilities of the Regional Transfusion Laboratories at my disposal. Very valuable technical assistance has been given to me by Herbert Gutfreund, B.Sc., who also prepared the solutions of bovine albumin. The ultracentrifuge runs were kindly undertaken by Dr. Ogston of Cambridge. The preparation of D.B.S. has been continuously in the hands of Mr. Harold Nevin, technical assistant in the department of surgery. Finally I am indebted to Dr. A. J. McCall, pathologist to the North Staffordshire Royal Infirmary, Stoke-on-Trent, for the "idea" of adding formalin and ammonia to serum to prevent coagulation.

## TREATMENT OF ANAEMIA IN SCHOOL-CHILDREN WITH IRON AND ASCORBIC ACID

BY

L. S. P. DAVIDSON, M.D., F.R.C.P.Ed.&Lond.

AND

G. M. M. DONALDSON, M.B., Ch.B.

In a previous survey of the haemoglobin levels of a cross-section of the population in Edinburgh (Davidson *et al.*, 1942) subnormal haemoglobin values were found in approximately 40% of children from municipal schools as compared with only 4.5% of children examined at private schools. Accordingly a therapeutic test was undertaken in order to evaluate the effect of adding supplements of iron and ascorbic acid to the diet of the municipal-school children. The results of this experiment have been submitted to Dr. A. Bradford Hill for statistical analysis, and the statement that a significant rise in the mean haemoglobin values has occurred in any of the experiments outlined below is based on that analysis. In each experiment the initial haemoglobin levels of the control

and experimental groups were not significantly different. The tests were carried out in three municipal schools on children from 5 to 12 years of age.

#### School I

The children in both the control and the experimental groups were unselected, but were divided into three groups according to whether they took school or home midday meals. Group A consisted of children who went home for a midday meal; Group B included those who took school dinners, for which they paid; while Group C included those children who had free school dinners. The children in the experimental groups were given 3 gr. of ferrous sulphate in tablet form daily for 5 days a week. Haemoglobin estimations were made at the outset of the experiment and again after three months of treatment. The results of the experiment are shown in the accompanying Table.

Table showing Mean Hb % in Control and Experimental Groups

	Total	Treatment Received	1st Examination	2nd Examination	3rd Examination
School I:					
Group A {	77	Ferrous sulphate 3 gr. daily	85.1	84.6	
Control	85		85.3	87.0	
" B {	32	" "	77.0	80.1	
Control	44		80.3	85.9	
" C {	41	" "	82.2	82.6	
Control	45		80.7	86.3	
School II:					
{	57	Asc. acid 25 mg. daily	81.7	80.8	
Control	56		82.4	82.0	
{	57	Asc. acid 25 mg. daily + ferrous sulph. gr. 3 daily	82.4	83.8	
Expt. II					
School III:					
Control	27	Asc. acid 25 mg. daily + ferrous sulph. gr. 6 daily	78.0	81.2	83.3
Expt.	27		77.8	87.3	93.5

#### Conclusions

(a) *Control Groups*.—There was no significant rise in the mean haemoglobin levels at the second examination.

(b) *Experimental Groups*.—In all three groups the mean haemoglobin levels at the second examination after three months of treatment were significantly higher than the corresponding figures for the control groups. In Groups B and C there was also a significant rise in the haemoglobin levels at the second examination as compared with the original haemoglobin values. In Group A, although there was a rise in the haemoglobin values, it was not statistically significant.

(c) An analysis of the haemoglobin figures of those children whose initial haemoglobin level was less than 80% showed that of 59 such children in the control series 31 (52.5%) still had haemoglobin figures of less than 80% at the second examination; while of 71 receiving iron therapy, only 24 (33.8%) still had haemoglobin figures of less than 80% at the second examination. This improvement in the treated group is statistically significant.

#### School II

(a) *Control Group*: total, 57 unselected children. (b) *Experimental Group A*: total, 56 unselected children; treated with 25 mg. of ascorbic acid daily for 5 days a week. (c) *Experimental Group B*: total, 57 unselected children; treated with 25 mg. of ascorbic acid daily and 3 gr. of ferrous sulphate daily for 5 days a week. Haemoglobin estimations were made at the outset of the experiment and again after three months of treatment.

#### Conclusions

(a) *Control Group*.—There was no significant rise in the haemoglobin values when the estimations were repeated at the end of three months.

(b) *Experimental Group A*.—There was no significant rise in haemoglobin levels after three months of treatment with ascorbic acid as compared with the initial haemoglobin values or with the control group.

(c) *Experimental Group B*.—There was a significant rise in the haemoglobin levels of the children on iron and ascorbic acid after three months of treatment as compared with the

control group, but the increase over their own initial haemoglobin values was not significant.

(d) An analysis of the haemoglobin figures of those children whose initial haemoglobin level was less than 80% showed that out of 26 in the control series 15 (57.7%) still had haemoglobin figures of less than 80% at the second examination; of those receiving ascorbic acid alone, 19 had haemoglobin levels below 80% at the first examination, and at the second examination 13 (68.4%) were still below 80%; while of those receiving iron and ascorbic acid 19 were below 80% at the first examination, but only 4 (21.1%) were below 80% at the second examination. The improvement noted in this last group is statistically significant.

#### School III

Only children whose original haemoglobin level was 80% or less were included in this experiment. (a) Control group, total 27. (b) Experimental group, total 27.

The children in the experimental group were given 25 mg. of ascorbic acid daily and 6 gr. of ferrous sulphate in tablet form daily for 5 days a week. It should be noted that the dosage of iron was double that given in Schools I and II, and the children were selected because clinical anaemia was present. Treatment was given for six months. Haemoglobin estimations were made at the outset of treatment and repeated at intervals of three and six months.

#### Conclusions

(a) *Control Group.*—A significant rise in haemoglobin levels was found at the second and third examinations as compared with the levels found at the first examination.

(b) *Experimental Group.*—This series also showed a significant rise in haemoglobin levels at the second and third examinations. The mean levels in this treated group were, however, significantly greater than those found in the control group at the second and third examinations.

#### Discussion

Investigations into the Hb levels of large numbers of persons in different areas of Great Britain, including Aberdeen (Davidson *et al.*, 1935) and Edinburgh (Davidson *et al.*, 1942), have clearly demonstrated the frequency with which anaemia occurs in infants, school-children, and women, both pregnant and non-pregnant. The anaemia is almost universally of the hypochromic type, which responds excellently to iron therapy. It leads to a feeling of fatigue and exhaustion, to a loss of appetite, and to a reduction in efficiency. In the case of the infants it has been shown to be associated with an increased liability to infection. The family doctor should constantly be on the watch for the development of anaemia in his patients. The improvement in their general well-being which will rapidly result from the administration of the ferrous salts of iron will amply reward him for the time spent on making the necessary examinations. For the prevention of anaemia, reliance should be placed primarily on securing an adequate intake of iron by instructing the patient to eat sufficient quantities of the foodstuffs which are particularly rich in the mineral. By so doing the intake of other important factors connected with haematopoiesis—e.g., protein and vitamins B and C—will be coincidentally improved. In this connexion we wish to draw attention to the value of national wheatmeal bread made of 85% extraction flour. Its content of iron is 0.7 mg. per oz., compared with 0.3 mg. per oz. for white bread made from 70% extraction flour. On an average intake of 6 oz. of bread daily an addition of more than 2 mg. of iron daily is consumed. Investigations which will be published shortly suggest that this increment during the past eighteen months has already made a significant contribution to the reduction of anaemia in school-children. Nevertheless, under wartime conditions it may on occasion be necessary to supplement the diet with medicinal iron.

The investigations reported in this paper clearly indicate that the administration of iron in doses of approximately one-third of that usually prescribed for curative treatment can significantly improve the haemoglobin levels of school-children. The increases shown in the Table are admittedly small. It might accordingly be asked whether any significant improvement in health could be expected to result therefrom. It should be pointed out, however, that the figures given represent mean

values. In the municipal-school children in Edinburgh the average haemoglobin figure was found to be 80%. Accordingly approximately half of the children had a haemoglobin level above this figure and half below it. It would be unreasonable to expect such small doses of iron to affect materially haemoglobin levels of normal or only slightly subnormal ranges. A study of individual cases showed this to be the case. It should be noted incidentally that when two tablets were given daily, as in School III, the mean haemoglobin was brought up to 93%. In the case of children whose haemoglobin was below 80%, and particularly when they were in the neighbourhood of 70%, a rise of 10 to 15% regularly followed the administration of one tablet of fersolate daily. It was due to these increments that the mean haemoglobin level was raised. Few would question the advantages to the health of school-children of such an increment.

It should be noted that the experiments recorded in this communication were essentially prophylactic in nature, and it must be clearly understood that in the treatment of individual cases of anaemia much larger doses of iron should be given.

Our knowledge of the aetiology, incidence, and treatment of iron-deficiency anaemia is now so complete that the medical profession must shoulder the responsibility if the necessary measures for its control are not widely adopted.

#### Summary

Experiments conducted over periods of three to six months indicate that a supplement of iron, even in such small amounts as 3 gr. of ferrous sulphate once daily for 5 days a week, can produce a significant rise in the haemoglobin levels of municipal-school children.

This suggests that the hypochromic anaemia of these children is mainly conditioned by an insufficiency of iron in the diet.

A supplement of 25 mg. of ascorbic acid daily had no effect in raising the haemoglobin levels.

We wish to express our thanks to Dr. Bradford Hill for his statistical help, and to Messrs. Glaxo Laboratories Ltd. and Roche Products Ltd. for their generosity in supplying free the supplements of iron and ascorbic acid respectively; and also to the Medical Officer of Health for Edinburgh and the staffs of the municipal schools, whose assistance was much appreciated.

## THE INFLUENCE OF SUPPLEMENTS OF VITAMINS A, B<sub>1</sub>, B<sub>2</sub>, C, AND D ON GROWTH, HEALTH, AND PHYSICAL FITNESS

BY  
E. R. BRANSBY J. W. HUNTER, M.D.  
H. E. MAGEE, M.B. E. H. M. MILLIGAN, M.D.  
AND  
T. S. RODGERS, M.D.

This is a summary of a vitamin feeding test carried out in 1941-2 on approximately 1,400 school-children and adults. A full report of the test has been prepared, but it is too lengthy for publication.

Towards the end of 1940 the Ministry of Health accepted a gift of multi-vitamin capsules from a group of United States physicians to carry out a feeding test on suitable groups of people. The time was opportune, and the capsules were employed as test material to ascertain whether a supplement of synthetic vitamins to the ordinary diet would improve growth, health, and physical efficiency. Each capsule contained:

Vitamin A ..	4,000 i.u.	Ascorbic acid ..	1,000 i.u.
Vitamin B <sub>1</sub> ..	333 i.u.	Nicotinamide ..	20 mg.
Riboflavin ..	2 mg.	Vitamin D ..	600 i.u.

Three of the five tests carried out were done on school-children and two on factory workers. Four times during the tests the vitamin content of the capsules was checked and found up to specification by the Medical Research Council. The school tests were performed on elementary-school children in Ipswich, Glossop, and London. The number of children who completed the test was 1,242: Ipswich, 425 boys and girls aged 5 to 13; Glossop, 370 boys aged 9 to 13; London, 447 boys

aged 9 to 14. Of the London children 123 were boys aged 9 to 14 living in a camp school.

The tests began in Nov./Dec., 1941, and ended in July/Aug., 1942. The school-children were examined before, during, and after the period of feeding. They were divided at random into two equal groups according to school, age, and sex; one group received a vitamin capsule every school day, and the other a capsule containing a similar quantity of arachis oil, which is practically devoid of vitamins. Records were kept of all illnesses, of their nature and duration. The medical examination included examination of the teeth and gums by dentists—in London by T. S. Rodgers.

The factory tests were conducted at the zinc-smelting works at A and L, where the labour is extremely strenuous and exhausting. The men work in gangs of five or six, and the average output of zinc for each gang is weighed daily. In factory A 12, and in factory L 24, gangs of workers were divided at random into a vitamin and a control group. Each man received an appropriate capsule six days a week. The naked weight was taken monthly before the men began work. Haemoglobin and blood pressure were also measured at regular intervals, and the output of zinc and all absences due to illness were recorded.

The findings for the children were similar in all four places. During the period of observation the vitamins had no statistically significant effect on the rate of growth, nutritional status, muscular strength, condition of the teeth and gums, or absence from school on account of illness. Muscular strength was measured in London and Glossop by a dynamometer like that described by Hill, Magee, and Major (*Lancet*, 1937, 2, 441); it was not done in Ipswich. In Glossop alone a special test of endurance by hanging on a bar was done. Both the controls and the vitamin children improved in endurance, and the improvement shown by the vitamin children was greater than that shown by the controls. In view of the relatively small number of Glossop children tested, we feel that this particular finding should be strictly limited in its application to that group of children. Similar findings would have to be obtained in other areas before any wider application of the Glossop results could be regarded as justifiable. Feeding tests with this object were started on several thousand children three months after the conclusion of the above tests, and are still in progress.

In the factory tests on 214 adult men, the results showed that the vitamin capsules had no significant effects on weight, haemoglobin, blood pressure, absence from illness, or output of material. The conditions of the test in the factories, however, were such that only relatively large differences in output would have been revealed.

Many people assisted us in conducting these feeding tests and analysing the results, but lack of space forbids individual acknowledgment of their help. A mass expression of thanks to all who co-operated is all we can make in this summary.

## UMBILICAL HERNIA IN CHILDREN WITH SPECIAL REFERENCE TO INJECTION TREATMENT

BY

M. J. BENNETT-JONES, Ch.M., F.R.C.S.

Honorary Surgeon, Bootle General Hospital and St. Helens Hospital; Visiting Surgeon, Whiston County Hospital

Umbilical hernia is classified into three types—congenital, infantile, and adult. There is no disagreement as to the treatment of the extremely rare congenital type, or exomphalos: all are agreed that it is only possible to save the infant from peritonitis by operating within a short period after birth. I have successfully operated on an infant within four hours of birth for an extensive exomphalos containing much large and small intestine: the defect in the abdominal wall was closed by the Mayo method, and it was surprising how the scar later contracted down and almost resembled a normal umbilical cicatrix.

The infantile and adult types are both of acquired origin; but they are regarded as being quite separate diseases. The general impression is that umbilical hernia rarely occurs in adolescence and early adult life. It is true that surgery is seldom requested for umbilical herniae at this period of life, because, if present, they are small and do not bother the

patient much. Few mothers will fail to seek medical attention for a large umbilical hernia in a child. The adult patient one has to deal with are more commonly females than males, and the preponderance of females appears proportional to the greater incidence of adiposity in the female sex. Although the patients are over 40 years of age they usually state that they know the hernia has been present many years; but its onset is always vague and insidious. It is therefore impossible to establish any clear relation between the presence of a umbilical hernia in childhood and one in later life.

### Clinical Features of Infantile Umbilical Hernia

The mother nearly always states that the hernia has dated from soon after birth, but occasionally a latent interval up to four months has been noticed. There is no history of any gross sepsis of the umbilical stump. The infant, either male or female, is often poorly developed, and is more likely to be suffering from rickets than the very rare condition of cretinism. It is important to keep in mind the possibility of increased intra-abdominal pressure due to ascites or intestinal obstruction, etc. The majority, however, have no obvious predisposing cause, but sometimes inguinal hernia is also present; adiposity apparently is not associated with infantile umbilical hernia. The infants are presented at a surgical out-patient department from 8 weeks old upwards, but the majority are about 18 months old when they arrive, having failed to respond to treatment by strapping.

### Treatment

Paterson and Gray (Barrington-Ward, 1937) found that out of 214 cases at the Hospital for Sick Children, Great Ormond Street, 101 disappeared without operation, but all writers say that the longer the hernia has been present and the larger the neck, the less likely will it be cured without operation. Few spontaneous cures occur after the age of 3 with support. As spontaneous cure with support occurs in nearly half the cases I thought injections would increase the proportion of and hasten cure in selected cases with small necks. My result seem to show that injections can cure umbilical hernia in such cases. The advantage of the treatment is that it may avoid operation and admission to hospital, and can therefore be advised for debilitated infants and children with small herniae. I think the main disadvantage is that the temperament of young children is rather unsuited to repeated injection if one is insufficient. There appears to be no risk of injecting into the peritoneal cavity.

Injection treatment of inguinal hernia was first practised by George Heaton (1877) of Boston, Mass., about a hundred years ago, but was later perfected by Ignatz Mayer of Detroit. Delisle Gray (1932), who advocated Mayer's technique, brought the method and the results before the medical profession in England. So far as I can ascertain from literature and hearsay evidence there have been few cases of umbilical hernia treated in this way. Burdick and Coley (1937), out of a total of 92 cases, treated only one umbilical hernia by injection, and the result of this was not stated. Wyss (1929), Larson (1934), and Quillin (1934) reported favourably on the result of injecting umbilical herniae, but they were all mainly concerned with adult inguinal hernia. Bratrud (1937) illustrated his technique of injections for umbilical hernia, and stated that by this method they were more favourable than even in indirect inguinal hernia. Personally, I have not yet tried injection for inguinal hernia because the many attendances for injection at an out-patient department would entail as much lost work as with operative treatment, and if the patient was not cured at the end of the time both patient and employer would be dissatisfied. With regard to inguinal hernia in children, the operative treatment is so safe, with recurrence and sepsis almost unknown, that I have not yet been tempted to try injection treatment. There is no doubt that even inguinal hernia can sometimes be cured by a truss in childhood—e.g. the famous case of Sir Astley Cooper (Murray, 1910), which was verified at his necropsy, when only a minute sinus can be found extending to the tunica vaginalis. In spite of this operative treatment is indicated because of the rarity of spontaneous cure.

It is the accepted view that umbilical hernia in children is nearly always curable with a support, but the cases seen

in hospital do not seem to respond to strapping. The cases of umbilical hernia I selected for injection had necks the smallest diameter of which was one-third of an inch or less. Most of the cases had been sent to me because strapping had failed.

#### Technique of Injection Treatment

An anaesthetic is not essential for young infants: a little ethyl chloride anaesthesia, however, is very helpful, because voluntary movements are controlled, but the sac still remains distended, so that it can be avoided. I have used up to 4.5 c.cm. of 5% phenol in almond oil at one injection. The solution is injected into the subcutaneous tissue as near the neck as possible without risk of puncture of the peritoneum. At a subsequent injection, if this is required, it is much harder to inject the solution. After injection it is essential to keep the hernia reduced. A small round pad of gauze is held in position by elastoplast applied right round the body like a belt at the level of the umbilicus. This support should be continued after the injections have ceased because the scar tissue produced by the sclerosing fluid becomes more strain-resistant as time progresses. Animal experiments (Crohn, 1937) have shown that the phenol solution produces tiny areas of necrosis, which are later followed by more intense fibrous reaction than that seen when other solutions have been tried.

I would like to emphasize the method of applying elastoplast as a complete belt. Beadnell (1942) has suggested applying elastoplast to one half of the abdomen as far as the midline while the nurse pushes the other half of the rectus muscle towards the middle. Beadnell admits that his method produces a fold of skin in the midline, so there will be no effective antero-posterior support and very little pull on the two rectus muscles when the child cries or strains. The belt method of application keeps the hernia effectively reduced without any skin-chafing, and it will give much more support to the hernia owing to fixation from the lumbar spine. Mothers of babies with umbilical hernia nearly always state that they have noticed that the baby has cried less than before, and the belt method has certainly not reduced the baby's appetite or increased its liability to vomit. I strongly recommend this method of support, even for the youngest babies, as soon as umbilical hernia is noticed. The ordinary binder slips either up or down and it has to be removed daily for bathing, so the hernia is not kept permanently reduced.

#### Results of Injection Treatment

With ages ranging between nearly 3 months and 5 years, 42 out of a total of 62 cases of infantile umbilical hernia were selected for injection treatment and 63 injections were given. 26 cases needed only one injection; 11 cases had two injections, but two of these were submitted to operation later because the hernia showed insufficient diminution in size; 4 cases had three injections, and only 1 case had four injections, but this resulted in a cure. Out of the 42 cases selected for his treatment 31 were apparently completely cured when seen later, excluding the 2 cases cured by operation after unsuccessful injections; 2 cases were untraced, but it was not certain that the remaining 7 were finally cured, although when last seen they were responding well and there was very little umbilical bulge.

#### Subcutaneous Ligature

This minor operative procedure is recommended by Fraser (1926) for small umbilical herniae, and especially if they occur in slightly debilitated children who might not stand the radical procedure. The same author states that he has had no recurrence in hundreds of cases. Others, including myself, have not found this method so certain, because there has been a recurrence after an interval. It is probable that I would have found it more successful if I had combined subcutaneous ligature with a post-operative belt support.

#### Radical Cure

Most writers state that the radical method is the only certain way of curing umbilical hernia if the patient is over 3. It is required, however, for large herniae below that age. Barrington-Ward (1937) does not advise the Mayo type of repair, because here is no wide separation of the fascia, and yet he states that the recti are separated. It is curious that I cannot find any textbook which mentions that the hole in the fascia is

more often elliptical, with the long axis transverse: in fact, it can often be described as a transverse slit. Surely this shows that the Mayo type of closure of the fascia is better, just as it has proved better in adults. In children it is unnecessary to excise the umbilicus with an elliptical area of skin as in the Mayo operation for adults, because the hernia is reducible.

After opening the sac at its neck it is often possible to sew up the peritoneum separately. The aponeurotic opening is then closed by mattress sutures with overlap. The most difficult part of the operation is dissecting the fundus of the sac off the deep aspect of the umbilicus without buttonholing it or leaving a portion of the sac behind. My impression is that it is better to buttonhole the skin than to leave any endothelial lining, which predisposes to haematoma formation and sepsis in spite of drainage. Recently I have not drained the wound but have applied elastoplast as a belt after the operation. This procedure obliterates any dead space, and appears to have reduced the incidence of slight wound sepsis. Because of the danger of collapse of the lung Fraser does not recommend this operation before the age of 3. Apart from local sepsis, which delays convalescence, I have had no complications, although I will undertake operation in much younger patients if the hernia is large. I have performed the radical operation in 30 children, with two recurrent cases, during the same period as the cases that were selected for injection treatment.

#### Conclusions

Infantile umbilical hernia should be treated as early as possible with elastoplast applied as a belt with a small pad. After the age of 3 months the combination of injection and support will give a large percentage of cures even if strapping has failed in about two-thirds of the cases sent to the surgeon. Ambulatory treatment is desirable if possible in children, because of the frequent shortage of children's beds through infectious diseases and because of the risk of cross-infection. The injection treatment appears safe if done under short general anaesthesia.

## Medical Memoranda

### Dienoestrol for Menopausal Symptoms

The chemical formula and physical properties of dienioestrol (7 $\beta$ -di-p-hydroxyphenyl- $\Delta^4$ -hexadiene) were recorded by Dodds, Golberg, Lawson, and Robinson (1938), and Campbell, Dodds, Lawson, and Noble (1939). Zuckerman (unpublished communication), working on monkeys, found that dienioestrol when given by injection was much less potent than the naturally occurring oestrogens. Emmens (1938) found that when this compound was given to mice by mouth it had the greatest activity, relative to subcutaneous dose, of any oestrogen examined up to that time.

A clinical trial with dienioestrol was carried out by me (Barnes, 1942). The compound was used for the inhibition of lactation, and its effect for this purpose was compared with that of stilboestrol and hexoestrol. The results showed that when given by mouth dienioestrol is a potent oestrogenic substance, and inhibition of lactation was obtained with one-tenth of the dose required in the cases of stilboestrol and hexoestrol. It was clear that further clinical trials were desirable to establish the value of dienioestrol as an oestrogenic agent, and it was therefore decided to try its effect in relieving menopausal symptoms.

Hawkinson (1938) as a result of the study of 1,000 women who were undergoing a natural or artificially induced menopause found that 75% suffered from distressing symptoms, but that considerable relief could be given by the administration of naturally occurring oestrogens. This has been the experience of many workers, and it has been found that the synthetic oestrogens are equally successful in relieving the symptoms.

The results are not easy to evaluate, as the symptoms complained of are largely subjective. In the present series an attempt was made to follow the patients' progress by means of repeated vaginal smears, but, unfortunately, the records are incomplete in this respect, partly because the patients were erratic in their attendances at the clinic.

#### THE PRESENT INVESTIGATION

The clinical results obtained in this small series may be summarized as follows: A total of 13 patients received treatment with dienoestrol, all for menopausal flushing or senile vaginitis. Two must be discounted, as they attended the clinic only once and were not seen again.

Of the remaining 11 five were having a natural menopause; one had had a surgical menopause for endometriosis at 38 years; two had had hysterectomy (presumably without removal of both ovaries) 14 and 15 years ago respectively; three had had a radium menopause. The symptoms and signs were: seven had hot flushes only; two had signs and symptoms of senile vaginitis; two had both conditions.

The results of treatment with dienoestrol, using a dose of 0.1 mg. by mouth twice daily for one or more periods of four weeks, were as follows: Hot flushes relieved or cured, 7 cases; hot flushes slightly relieved, but responded better to stilboestrol (1 mg. twice daily), 1 case; hot flushes not relieved by dienoestrol but cured by stilboestrol (1 mg. twice daily), 1 case. Larger doses of dienoestrol would probably have been effective in these two cases. Senile vaginitis was relieved or cured in all the four patients treated for this condition.

As already mentioned, an effort was made to obtain objective evidence of the effects of treatment by means of serial vaginal smears. A smear was taken at each attendance—that is, every four weeks. In three patients the senile change was not sufficiently advanced before treatment was begun to say that there had been any change. In three others there was definite evidence of an oestrogenic effect, but in the remaining five the changes were too indefinite to warrant any conclusion.

All the patients were carefully questioned for toxic effects. None experienced nausea or vomiting. One patient had a slight vaginal haemorrhage. One other patient stated that the tablets "made her feel depressed," and she stopped taking them. Her hot flushes were subsequently relieved with stilboestrol.

#### CONCLUSIONS

It is unfortunate that it has not been possible to make these tests in a larger series of menopausal patients. The results obtained in this small group indicate, however, that dienoestrol is a safe and non-toxic oestrogen; and it is to be hoped that it will be possible for other workers to carry out more extensive trials.

This investigation was carried out in the Obstetric Unit, University College Hospital, on behalf of the Therapeutic Trials Committee of the Medical Research Council. Pressure of other duties has prevented my testing dienoestrol in a larger series of menopausal cases, and the present Memorandum is therefore published mainly as an encouragement to other workers to continue the tests.

I am indebted to Messrs. Boots Pure Drug Co. Ltd., British Drug Houses Ltd., and Glaxo Laboratories Ltd., for supplies of dienoestrol.

JOSEPHINE BARNES, D.M., F.R.C.S., M.R.C.O.G.,  
First Assistant, Obstetric Unit, University College Hospital.

### "Inspiratory Borborygmi" as a Sign of Diaphragmatic Hernia

The diagnosis of diaphragmatic hernia has been made with increasing frequency in recent years, and it has come to be recognized as a not uncommon cause of obscure respiratory and abdominal symptoms. The symptoms are, however, in no way distinctive, and signs are in many cases indefinite or entirely lacking. As a result these patients are often wrongly diagnosed, and may even be subjected to operations without the true nature of the condition being recognized. Harrington (1938) found that in a series of 123 cases of diaphragmatic hernia an average of 3 previous erroneous clinical diagnoses had been made, and operations for gall-stones and gastric ulcer had frequently been carried out without relief. Diseases of the thorax, abdomen, or blood (hypochromic anaemia) may be simulated, and for this reason diaphragmatic hernia has been termed the "masquerader of the upper abdomen." In a case recently under my care the diagnosis was suggested by a sign which I have not seen previously described.

#### CASE RECORD

The patient, a woman of 74, was admitted to St. Nicholas Hospital complaining of cough and dyspnoea. She gave a history of migraine from puberty to the menopause, and strangulated inguinal hernia 10 years ago. Apart from this she was well till 5 years ago, when she began to have attacks of cough and breathlessness lasting 4 to 6 weeks at a time and recurring about once a year. An attack was preceded by a grunting noise in her stomach which she felt with each breath. She also suffers occasionally from pain in the left chest and back. For the last 8 months she has been increasingly short of breath on exertion, and if she eats a big meal she has abdominal pain and a sense of suffocation, and has to sit down and rest for a time. Several days before her admission to hospital she noticed the usual grunting noise in her stomach. This was followed by vomiting, and diarrhoea, and later by cough and dyspnoea. A few days after her admission the attack had passed off, but she complained of pain in her left chest passing through to the back. On examination she was found to be a fairly well nourished woman. She lay flat in bed and was in no obvious distress. A grunting, borborygmus-like sound synchronous with inspiration could be constantly heard coming from her abdomen during the examination. With the stethoscope this sound was found to be most readily audible over the left lower chest and epigastrium. It ceased when the patient held her breath or sat up. Physical examination, apart from some moist sounds at the bases of the lungs, was negative. The blood pressure was 160/85.

FIG. 1.—Antero-posterior view. Hernia can be seen lying behind lower part of heart shadow.

FIG. 2.—Lateral view. Hernia is seen to pass up into the posterior mediastinum in front of the oesophagus.

A barium meal revealed a shadow superimposed on the lower part of the heart shadow in the supine position (Fig. 1). In the erect position it was seen to empty during expiration and fill with barium from below at each inspiration. The hernia was observed to contain a portion of the cardiac end of the stomach and to be situated in the posterior mediastinum in front of the oesophagus (Fig. 2). It was therefore a para-oesophageal hiatus hernia, according to Akerlund's (1926) classification.

#### DISCUSSION

"Gurgling at the left base" has been mentioned in several accounts of the disease; but it is not diagnostic, as it is heard in many other conditions and in normal subjects by transmission of the sounds from the abdomen. Unless the gurgling sound is heard in the left side of the chest, is synchronous with respiration, and stops when the breath is held it is not diagnostic. The mechanism by which this sign is produced is simple. During inspiration the intra-abdominal pressure is increased. At the same time the pressure in the thorax becomes more negative. As a result gastric contents, both fluid and gaseous, are forced into the herniated portion of the stomach, so producing the gurgling sound. If in the upright position the fluid level in the stomach is below the opening into the herniated pouch, only gas will pass to and fro and so the sign will disappear, returning when the patient lies down again. I have not encountered this sign in any other disease.

**Addendum.**—A further case of diaphragmatic hernia in which this sign was present has since been encountered. This was also a hiatus hernia, but of the gastro-oesophageal type, the lower end of the oesophagus being pushed up through the hiatus as well as the fundus of the stomach. The sounds were best heard over the precordium, the patient lying on her left side.

I wish to thank Dr. Allen Daley, Medical Officer of Health to the London County Council, for permission to publish this paper; and Dr. F. J. Power, medical superintendent of St. Nicholas Hospital, for facilities granted.

J. STEWART LAWRENCE, M.D., M.R.C.P.,  
Physician to an Emergency Hospital.

## Reviews

### SURGERY OF REPAIR

*The Surgery of Repair: Injuries and Burns.* By Squadron Leader D. N. Matthews, R.A.F.M.R., M.D., M.Ch., F.R.C.S. (pp. 386; illustrated, 45s.) Oxford: Blackwell Scientific Publications Ltd. 1943.

It is a little difficult to know for whom this book is written. The student will find it an interesting and readable account of surgery of repair. The general surgeon will probably be interested in Part I and Part IV and leave the middle portion to the specialist, who in his turn will find this section somewhat inadequate.

Part I deals with the immediate treatment of injuries, and attempts to cover all the ground that has been written on so fully in the last few years. It discusses shock, crush injury, chemotherapy, anaesthesia, the surgery of wounds, nerve and tendon suture, abdominal and chest injuries. Shock is defined in two lines. Would that it were so simple! There is a noticeable tendency to make terse, dogmatic statements on debatable issues. A chapter on fractures of the mandible and fracture of the facial bones is valuable, but this could well be expanded. Part II describes late repair, including scar excision and the many varieties of skin transplantation. These are handled quite well, but without sufficient emphasis on the difficulties that lie in the path of the beginner. Nerve and tendon injuries get another chapter, but there is no warning of tourniquet paralysis, of the bad results of cut flexors, the weakness of catgut, the disappointments of annoplastin, the unreliability of the reaction of degeneration, or Tinel's sign. Part III is devoted to the repair of facial injuries. Operations are described for dealing with the nose, the lips, the eye, the cheek, etc. Each could do with a book to itself. Such have, indeed, been written. It is quite impossible to cover the field in a book of this size, and the reader should be warned that the repertoire is limited. Part IV is an adequate summary of the treatment of burns, but once again the field of late repair is inadequately covered.

The whole book gives one the impression of being too facile and unfinished. It is a pity that the author takes liberties with proper names, with anatomical nomenclature, and with the English language by using such words as "inrolling" and "pedieled" as verbs.

### BORDERLANDS OF PSYCHIATRY

*Borderlands of Psychiatry.* By Prof. Stanley Cobb. Harvard University Monograph in Medicine and Public Health, No. 4. (Pp. 166; illustrated, 52.50.) Massachusetts: Harvard University Press. 1943.

This is a very readable exposition, consisting of a series of lectures on the body-mind relationship, and especially the brain-mind relationship, in its bearing on disease. The chapter headings—Body and Mind; Parallel Evolution of Speech, Vision, and Intellect; Speech and Language Defects; The Function of the Frontal Areas of the Human Brain; Anatomical Basis of the Emotions; Consciousness; Concerning Fits; Psychoneurosis; Psychosomatics—indicate its scope. The author's general point of view is embodied in the following sentences: "My personal belief is that consciousness . . . is a function of nervous tissue in action, just as contraction is a function of muscle." "My guess just now is that consciousness will sooner or later be described in terms of electronic activity." His approach is therefore essentially neurophysiological, but his presentation is tolerant and well balanced.

Stanley Cobb's explanation of the *modus operandi* of leucotomy is that it depends essentially on cutting out the long-circuiting process which is made possible by the cortex, and that the extent of its effects depends on the number of fibres destroyed.

### A PRIMER ON FOOD FOR AFRICA

*Food. A Primer for Use in Schools, Colleges, Welfare Centres, etc., in Africa.* By Sir Robert McCarrison, M.D., F.R.C.P., and Desmond Fitzgerald Moore, M.R.C.S. (Pp. 116. 2s. 6d.) London: Macmillan and Co. 1943.

The children of Africa to whom this book is dedicated may understand much of what is written in it without supplementary explanation from their teachers, but it will be slow going and dull without discussions and experiments, for it is concisely written and every sentence is a bald statement of fact. Different "lessons" deal with the various components

of food—namely, proteins, fats, carbohydrates, minerals, and each of the vitamins A, B (complex), B<sub>1</sub>, B<sub>2</sub>, P-P, C, and D; with the teeth and gastro-intestinal tract; with the amount of food needed; and with the more common foods, such as cereal grains, tubers and roots, green leaf vegetables, fruits, and vegetable oils, pulses, milk, meat, fish, liver, kidney, egg; and with faults in African diets. The table of food values at the end gives the protein, fat, and carbohydrate content in grammes per ounce, calorie value, and approximate vitamin value—as 0, V.L. (very little), one, two, or three pluses—of the common foodstuffs of Africa. The book is well printed and bound in soft green linen.

### Notes on Books

Dr L. J. HALPERN of Illinois has written a small volume entitled *How to Raise a Healthy Baby* (Hutchinson's Scientific and Technical Publications; 8s. 6d.) which is intended for parents. It is composed on the question and answer principle, and the information contained seems sound except for a dangerous-looking illustration of a baby having its ears and nose cleaned the *wrong* way. Practitioners may like to recommend it to their patients after looking at it for themselves.

The immediate care that can be given to injured persons at the site of a disaster and methods of transporting them to safety and medical attention are described in a new manual, *Emergency Care of Injured*, issued by the Medical Division, Office of Civilian Defense, Washington. The work is based on procedures and organization developed by the O.C.D. and careful study of three years of British and other air-raid experience. The 117-page book is divided into three parts; "Civilian Defense," "Emergency Field Care," and "Transportation of the Injured."

### Preparations and Appliances

#### A THORACIC ASPIRATING DEVICE

Dr. CLIFFORD RILEY, resident medical officer, Birkenhead Municipal Hospital, writes:

Aspiration of pleural effusion is a surgical procedure which the practising physician frequently has to employ. Various ingenious devices have been evolved to perform this function, they being often either laborious to use or expensive and complicated and "requiring a wheelbarrow" for transport. The device shown in the accompanying illustration has been designed to overcome many of these disadvantages; it consists of two non-return ball valves mounted in a brass casting, with

a side tube to take a standard 20-c.c.m. Record syringe. A rubber tube leads from the suction side to the needle in the chest wall, another leads from the delivery side to a receiver. In use, the handle of the syringe is simply pulled in and out. The whole apparatus will fit into an ordinary 20-c.c.m. syringe box and can be boiled.

Since its construction four months ago the device has been in constant use in the Birkenhead Municipal Hospital and has never failed to function satisfactorily. It aspirates thick pus of the nature of pneumococcal empyemata with ease, and has been found in practice to empty a pleural cavity in about a quarter of the time required by our "Potain" aspirator.

I wish to thank Mr. Grant for his note of appreciation of this device and for his interest in its development, and also Messrs. Alexander and Fowler, of Pembroke Place, Liverpool, who are producing it, who assisted with its development, and who supplied the illustration.

Mr. R. A. GRANT, M.B., F.R.C.S.Ed., medical superintendent of the hospital, writes:

The above ingenious device, invented by Dr. Riley, is in my opinion a considerable advance over any other appliance used for evacuating fluid from the pleural cavity. I have been impressed with the speed and ease with which pleural fluids can be drawn off. It is small, compact, and would be of equal benefit to general practitioners as to hospital medical officers. There is no complicated mechanism to go wrong, and it can be used in conjunction with any Record fitting syringe.

## Nova et Vetera

### HARVEY'S TEACHER AS EMBRYOLOGIST

*The Embryological Treatises of Hieronymus Fabricius de Aquapendente. The Formation of the Egg and of the Chick (De Formatione Ovi et Pulli). The Formed Fetus (De Formato Foetu). A Facsimile Edition, with an Introduction, a Translation, and a Commentary by Howard R. Adelman. (Pp. 833. \$12.00 or 72s.) New York: Cornell University Press; London: Oxford University Press.*

Fabricius of Aquapendente (1533-1619) is known to many as the teacher of Harvey at Padua. His investigations of the veins and of their valves undoubtedly put Harvey on the line of his great discovery. Fabricius has, however, many other claims to remembrance. He was equally accomplished in the practical arts of medicine and of surgery, and he produced the first attempt at a physiology of the special senses as well as several investigations of the organs and functions of speech, of respiration, and of movement. Scientifically his greatest achievements were undoubtedly his treatise *On the Valves of the Veins* (1603) and his two surviving embryological monographs. Prof. Adelman here presents us with the embryological works. He has accomplished his task in this beautiful volume in a way that is beyond criticism. Could all scientific classics be thus set forth, the study of the history of science would pass to a new phase.

Fabricius had intended to issue and had substantially completed a comprehensive treatise on embryology. The first part was devoted to the organs of generation and their mode of action. It has been lost. The second part treats of what Fabricius regards as the process of formation of the embryo, and was in effect a painstaking study of the development of the hen's egg. It was issued in 1621, two years after his death, and has certain obvious hiatuses. The third part, the only one that he himself saw through the press, is *On the Formed Foetus*. It appeared in 1604 and contains comparative accounts of the later embryos of a number of species, including man. Prof. Adelman reproduces both these treatises in facsimile together with a full translation into English. To these he has attached many illuminating notes, a well-conceived biography of Fabricius, and a general history of embryology to the seventeenth century. He has added a painstaking bibliography and a very detailed index. The whole comprises a most attractive book of over 900 pages.

#### Fabricius the Man

Prof. Adelman is certainly no hero-worshipper. Fabricius appears here as an entirely human and credible figure: a rather crotchety professor, intellectually active but physically indolent; more interested in research than in lecturing; peppery and at times indiscreet, but certainly not vindictive; over-optimistic as to his own powers and sometimes a trifle contemptuous of those of others. He was rather absent-minded and inclined to take his duty to his university more lightly than his duty to science, but, nevertheless, he was responsible for the building of the famous anatomical theatre at Padua, and, it is said, at his own expense. He was an excellent teacher, but only for those who wished to learn, which is but to say that most students would call him a very bad teacher! Only when he could bring himself to the effort did his class-teaching reach a high standard, and his best efforts were given to his private courses. Among his pupils were most of the distinguished anatomists of the age—such as Salomon Alberti, Caspar Bartholin, Caspar Bauhin, Giulio Casserio, William Harvey, Pieter Pauw, Adriaan van der Spiegel, and Olaf Worm.

#### A Conservative Philosophy

The positive achievement of Fabricius in the works here edited is very great, and it is almost an excess of the scholar's caution in Prof. Adelman that he does not reckon it as highly as have some of his predecessors. Fabricius was, after Aristotle, the founder of embryology as a rational discipline and as an observational science. But it is unfortunate that so fine an observer should have been perversely conservative in his theoretical views, and it is yet more unfortunate that he should have infected his pupil Harvey with similar qualities. Reading these works of Fabricius by the side of Harvey *On Generation* one cannot feel that the Englishman has advanced greatly on

his teacher, and in certain respects he has even receded. The Achilles heel of Harvey, the superb experimenter, was his obstinately conservative philosophy. Men of science have sometimes thought more about philosophy than is good for their special study. The intellectual lustre of both Fabricius and Harvey is a trifle dimmed, as against certain of the men of their age—as, for example, Vesalius, Sievin, Galileo, and Kepler—by their nostalgia for antiquity. How much more Harvey and Fabricius might have achieved had they known no more of Aristotle and Galen than did Leonardo! What a revolution it was when the Royal Society, a generation later, cut the cable that tied men to the ancient world with the new slogan *Nullius in verba*—"By the words of no man"! Fabricius and Harvey were very great men, but, as Prof. Adelman shows, they must rank just a little below those who had shaken themselves free from the whole tradition of antiquity. Harvey's inspired vision was neither sustained nor repeated. Fabricius, first-class observer though he was, never had the vision. We believe that in saying this we are not misinterpreting the thought of Prof. Adelman.

### A SIXTEENTH-CENTURY SICILIAN PHYSICIAN

The recent prominence in the war news of Sicily and especially of the town of Ragalbuto brings to mind that this town was probably the birthplace of Giovanni Philippo Ingrassias, who was born in 1510. He studied medicine at Padua, graduating from there in 1537. He soon became well known in Italian medical circles and was called to the chair of medicine at Naples. It was at Naples, in 1553, that he published a book entitled *De Tumoribus praeter Naturam*, in which he gave what is the first authentic account of scarlet fever. This disease was known among the countryfolk as "rossalia" or "rosania," and is described by Ingrassias as consisting of "numerous spots, large and small, fiery and red, of universal distribution, so that the whole body seems as if on fire." Scarlet fever was at this time confused by others with measles, but Ingrassias differentiated the two maladies thus: "Some there are who think that measles is the same as rossalia, but we have often seen with our own eyes, that they are different, not trusting to the description of others." He also gave a short description of chicken-pox in the same treatise. His account of this ailment occurs during his discussion on measles and rossalia: "... the other, *crystallos*, which since, as is known, reddish pustules break out and are dispersed over the whole body, the size of a pea, more or less, white and of a shiny crystal appearance which when they are opened one sees an aqueous fluid escape."

Ingrassias returned to Sicily and took up his abode in Palermo in 1560. In this city he became so celebrated that he was called the Hippocrates of Sicily. So great was his fame that he was appointed physician-in-chief to Sicily and the neighbouring islands by King Philip II of Spain in 1563. Ingrassias taught not only medicine but also anatomy, and anatomists associate his name with the lesser wings of the sphenoid bone, and he is accepted as being the first to describe the stapes of the middle ear. During his residence in Palermo, Sicily was ravaged by a severe epidemic of plague, and Ingrassias rendered great service during this crisis. He was offered a pension as a reward for his services, but this he declined—an action so unusual that it is recorded in accounts of his life. He was a prolific writer on many medical topics, both clinical and educational. He died in 1580.

H. P. TAIT.

The *Journal of the American Medical Association* announces that a permanent memorial to William Beaumont (1785-1853), known as the founder of modern knowledge of the physiology of the stomach, has been assured by the transfer of the historic "Enry House" on Mackinac Island to public ownership. In this house the young Canadian half-breed Alexis St. Martin, who was the subject of Beaumont's famous studies, received his accidental shot-gun wound on June 6, 1822, which caused a permanent gastric fistula. In the work of restoring the house technical advice will be given by a committee of the Michigan State Medical Society, the National Park Survey, and other agencies and historical sources.

W. Wespi (*Schweiz. med. Wschr.*, 1943, 73, 1257), who records an illustrative case, states that six cases have hitherto been reported of damage to the peripheral and central nervous system following "sedormid" (allylisopropylacetyl-carbamide). Wespi's case was that of a woman aged 21 who developed toxic polyneuritis after suicidal ingestion of 30 tablets. Recovery took place after several months' illness.

## EDUCATION BILL: THE SCHOOL MEDICAL SERVICE

The care of the health and physical welfare of school-children became a function of local education authorities when the Education (Administrative Provisions) Act was passed in 1907. It was extended by the Education Act, 1921. The scope of the authorities' duties and powers has been laid down from time to time by Regulations of the Board of Education, and includes obligatory medical inspection of both elementary and higher school children, and arrangements for attending to the health and physical condition of children, which are obligatory in the case of elementary but optional in higher schools. These latter arrangements have been defined by regulation as including the following-up of cases of defect found at inspection, the detection and prevention of uncleanness, and the medical treatment of defects of the eyes and teeth, minor ailments, and enlarged tonsils and adenoids. In fact most authorities, and virtually all the larger ones, have adopted schemes, with the approval of the Board, which provide for a further extensive range of treatment—for instance, of cripples, children suffering from diseases of the special senses like otorrhoea, from speech defects, and from incipient psychoneuroses. Some orthopaedic hospitals are largely maintained by payments or contributions from local authorities, exercising their dual responsibility for children of both pre-school and school ages. The only specific limitation of the powers of these authorities, as defined by law, is an embargo on their establishing a general domiciliary service of treatment by medical practitioners.

It is difficult to assess in precise terms the benefits derived from the school medical service, but there can be no doubt that it has played a large part in the improvement in the health, physical well-being, and cleanliness of children as compared with thirty years ago. Its work has been as much educational as diagnostic or therapeutic or directly preventive. The excessive claims on its behalf which are sometimes made by lay persons do not originate from school medical officers themselves, but it is significant that teachers—to whom this service brought work, trouble, and disturbance of routine, and who are in a good position to observe results—are among the strongest advocates of its continuance and expansion. For medical officers keenly interested in minor departures from anatomical, physiological, nutritional, and psychological averages it has proved an engrossing field of work, and indeed it has been almost the only wide field for the constant promotion of health in the positive sense. Many, however, have latterly been chafing at the dull routine of much of the

work. It is at least evident that attention to some of the minor ailments they deal with would not have fallen to clinics instead of the family doctor but for the fact that this attention was obtained free or at little cost.

The Education Bill does not set out to change the school medical service but rather to extend its application, although there is a hint, which has been made a little more explicit by a recent statement of Mr. Butler's in Parliament, that such change may come with the establishment of a comprehensive medical service for the nation. There are points of wording in the relevant clauses that deserve careful attention. For instance, the phrase "attending to the health and physical condition" in the Act of 1921 is eliminated and replaced by a blunt reference to medical treatment, which is defined as "treatment by any duly qualified medical practitioner or any person registered under the Dentists Act, 1878." In its context this clearly includes, for the present, treatment by school medical officers and school dentists, and it is evident that school medical inspection and other medical duties are to be carried out by officers employed or engaged by the education authorities. Nevertheless, the duty of an authority is stated in broad terms—viz., "to make such arrangements for securing the provision of free medical treatment for pupils in attendance at any school or young people's college maintained by them as are necessary for securing that comprehensive facilities for free medical treatment are available to them under this Act or otherwise." This seems to make it possible for the treatment of school-children to become, as it ought to be, part of a comprehensive medical service for the people, and not a direct function of education authorities. But medical inspection of all school and college children remains definitely a duty of the authorities. It may not be practicable to perform this duty without employing medical officers specially for the purpose—a position which will raise questions as to the desirability of relegating large numbers of young medical men and women to work entirely divorced from the clinical activities which maintain their interest in medicine. This is a difficulty which must be faced in planning the details of any future service of a general kind.

Treatment does not include treatment at the pupil's home; but otherwise, it will be observed, is to be entirely free of charge. These clauses apply as from April 1, 1945. Unless, and until, a comprehensive medical service for the people is in being, the new provision may cause curious anomalies. The parents of a pupil who is not confined to bed at home will be entitled to demand free treatment for him at either a clinic or a hospital. Indeed, unless the approved "arrangements" specifically prohibit treatment at the surgery of a private practitioner and provide as an alternative adequate facilities for the treatment of ambulatory illness of all kinds among pupils, it seems possible that the parents could ask the authority to foot the family doctor's bill for other than domiciliary treatment. Further, the responsibility would seem to extend to the cost of treatment in voluntary as well as municipal hospitals unless education authorities specifically inform parents that they disapprove of such treatment. Does this mean that education as distinct from health authorities are to enter forthwith into contracts with the managers of these hospitals?

Or, more probably, does it imply that the Government proposes that a comprehensive medical service shall be in operation by April 1, 1945, so that in any case by that time no parent would be called on to pay for the medical treatment of his child? But if this surmise is right, why the exclusion of domiciliary treatment from the free service? The financial memorandum suggests that, however the medical service is provided and administered, the cost will fall on education funds, for it is estimated to involve after seven years an increase in the annual expenditure on education of £6.5 million; but perhaps the inauguration of a general medical service would be accompanied by a transfer of these and existing costs to the appropriate account.

Certain clauses of the Bill mention the school medical officer, but his status is not defined beyond the requirement that he must be a duly qualified medical practitioner. The Minister has power to make regulations which may prescribe that certain examinations shall be carried out by an officer with special qualifications and specially selected for the purpose with the Minister's approval. It may be noted that, whereas the financial regulations relating to the school medical service are the responsibility of the Minister of Health—though this function may be given to the Minister of Education by "arrangement" as at present—the latter is given the regulating power as to the special qualifications mentioned above. The need for abolishing the power of local authorities to subordinate the medical officer to another non-medical official is not met in this Bill; it is an administrative question which the British Medical Association has frequently raised but which may perhaps lend itself more appropriately to regulation.

The administrative provisions contained in the Bill may indicate how the Government's mind is running in other spheres. The President of the Board of Education becomes the Minister of Education, with all the adjuncts of a Ministry. Advisory councils are to be set up separately for England and Wales, the members being appointed by the Minister on the basis of their experience in education. Locally the authorities are the county and county borough councils; but the former may, if they care and if the Minister sanctions, delegate all or any of their executive functions to "divisional executives," although they must remain themselves responsible for borrowing money and raising a rate. Although a county and county borough education committee, to which educational matters shall stand referred, must be established, and must include persons of experience in education so long as the majority of the members are councillors, there is nothing in the Bill to ensure that the divisional executives will contain knowledgeable persons except the Minister's power to modify a scheme. The Minister may also by order constitute a joint education board of two or more major authorities, consisting entirely of members of these authorities, but under the same obligations as to the establishment and constitution of an education committee. It seems unlikely that this piecemeal system of combination on the one hand and delegation on the other for special purposes will go far to meet the clamant need for a general reform of local government.

## MALARIA AMONG TROOPS IN WEST AFRICA

Few countries have a worse reputation for unhealthiness than West Africa, and by "unhealthiness" in the Tropics is always meant malaria. Now that troops in numbers as never before are stationed or operating in some of the most malarious countries in the world it is very important to know what clinical types of malaria are characteristic of such regions. This is so not only that medical officers having to treat cases of malaria perhaps for the first time should know what kind of cases to expect and look out for, but also to give guidance in treatment, convalescence, invaliding, and other arrangements for the medical care of troops. We might also reasonably expect to gain some clue to the effectiveness of suppressive drug prophylaxis and the adequacy of preventive measures as brought to bear in such areas. Further, it is important to know the relative frequency of the different clinical types, and above all what is the most usual class of case being admitted to hospital under such conditions.

It is information of this kind relating to a particular locality in West Africa that has been most adequately given in a paper published in this issue of the *Journal* by Capt. S. B. Hughes and Lieut.-Col. R. R. Bomford. These authors make an analysis of cases seen by them among British troops in two military hospitals in West Africa during 1941 and 1942. The analysis deals with 846 unselected cases. Of these 818 fall within five recognizable types. Of the remainder, 24 were particularly mild cases in which the patients had no fever and complained only of quite minor symptoms, and 4 were cases having jaundice as the principal feature. It should perhaps be noted here that infections other than those of malignant tertian malaria were rare and usually contracted outside the area. Of the 818 typed cases no fewer than 684 were of the "febrile type" (Type 1). These cases, judging by the symptoms described, were what might be called ordinary attacks of malaria such as are common enough among civilian residents and which, as an occasional illness, and apart from frequent repetition, are neither in themselves very serious nor permanently incapacitating to the individual. Vomiting was one of the most distressing concomitants, but was present in only about one-third of the cases. The hot stage lasted from 10 to 36 hours—a very usual period for malignant tertian—and was characterized by the usual high temperature, discomfort, and in some cases prostration. Of the second type, the gastro-intestinal, 11 had vomiting as the chief symptom, 24 were diarrhoeic, and 12 had blood and mucus in the stools. There were 39 of the respiratory type (largely bronchitis), and 10 of the myalgic type with muscular pain and stiffness; 2 only had cerebral symptoms, both cases completely recovering. In less than 10% of all the cases, the authors say, could the patient be described as severely ill, and in less than 1% as dangerously ill. Only 4 developed blackwater fever, of whom 2 died. All the cases were in males aged 18 to 51, who for the most part were in a malarious area for the first time. All were under the observance of antimalarial precautions and the taking of suppressive drug, so far as this could be ensured by disciplinary measures.

It must be admitted that the picture is startlingly different from that gained from descriptions of clinical types of malaria in West Africa as given in many of the older accounts. It is even surprising from the modern standpoint. The conditions in West Africa, so far at least as the coastal belt is concerned and for some hundreds of miles inland, are those now commonly described as hyperendemic—i.e., applying the term strictly, the indigenous population is in a state of almost universal infection, indigenous adults, by reason of immunity acquired in childhood, being largely free from active manifestations of the disease. In such areas European and other immigrant stranger communities, however, suffer very severely not only from malaria but from blackwater fever the result of such malaria. It is not often that European troops on any scale have been exposed to these conditions, though we have a few examples such as the Ashanti Expedition, which, though (like most tropical campaigns) of only some months' duration, was nevertheless a classical example of what malaria can be in such circumstances. That blackwater fever cases in the present instance were so few is to some extent understandable, since this condition rarely develops until after some considerable period of residence, and its occurrence might be expected to be lessened where proper hospital treatment replaced the self-treatment as usually practised by the civilian resident community in such areas. But even so the incidence is less than one might have expected, while the virtual absence of cerebral and other pernicious forms is very noticeable. The authors do not state in what part of West Africa their observations were carried out. But assuming that it was in the malarious coastal zone it is relevant to note that the troops concerned were not only under suppressive treatment during their stay in the country but were subject to other preventive measures. It is not, therefore, beyond the bounds of probability that these measures were responsible for the relatively mild type of infections encountered. It might be asked, then, why our troops should have suffered so severely in the last war in countries where malaria was essentially not more heavily endemic than in West Africa and where protective action was also taken. The answer, we hold, is that it is only in this war that the command and the troops themselves have become really "malaria-conscious," and as a result the measures adopted have been far more thoroughly thought out, carried out, and enforced; and it is not so surprising to believe that they have been correspondingly effective.

### REINTEGRATION AT LINCOLN'S INN FIELDS

The Council of the Faculty of Radiologists has decided that on March 25 the headquarters of the Faculty will be moved to 45, Lincoln's Inn Fields, premises belonging to the Royal College of Surgeons of England. Several clinical associations will make their headquarters in the same building, and a joint secretariat will be established. The associations which have decided to take part in this development are the Association of Surgeons, the British Orthopaedic Association, the Association of Anaesthetists, the British Association of Oto-Laryngologists, and the Council of British Ophthalmologists. The *British Journal of Surgery* also will have an office in the building. Meetings of

committees will be held in the associations' own rooms; councils and general meetings will take place in the Royal College of Surgeons, next door but one to the new offices. The Royal College of Surgeons welcomes this plan, which is designed to establish closer union between specialist departments and general medicine and surgery, and the College will give every possible assistance to ensure the success of the undertaking.

### MORE LIGHT ON THE B COMPLEX

In 1940 Van Etten and others<sup>1</sup> found that the administration of an ample supply of crystalline vitamin B<sub>1</sub> did not prevent convulsions and nerve degeneration in swine fed on autoclaved liver and whey. The experiments of Wintrobe<sup>2</sup> carry the matter a stage further, with an accurate description of symptomatology and pathology in pigs receiving all the known members of the B complex except B<sub>1</sub>. The earliest clinical manifestations were failure of appetite and vomiting, followed by cyanosis, dyspnoea, and bradycardia, and ending with a severe degree of heart failure or sudden death. No abnormality of neuromuscular disturbance, such as ataxic gait, was ever observed. Careful histological examination of the nerve tissues, central and peripheral, gave no evidence of degeneration or inflammation, but in practically every case local necroses of the myocardial fibres were present in both auricles and ventricles. Where the pathological condition had not advanced too far, administration of B<sub>1</sub> led to recovery. Of particular interest are the biochemical findings. The concentration of carbonyl compounds estimated as pyruvic acid was proportional to the degree of severity of the deficiency as judged by the clinical manifestations. A sharp rise in blood pyruvic acid was quickly followed by the rapid progress of the disease. It was also found that a significant increase in blood pyruvic acid after the administration of glucose always occurred in B<sub>1</sub>-deficient animals but not in the control group. As for urinary content of B<sub>1</sub>, it reflected—but by no means consistently—the dietary intake immediately before the collection of urine. Of more value in assessing the degree of B<sub>1</sub> deficiency was the percentage retention of B<sub>1</sub> after a given dose. This test, suggested by Najjar and Holt,<sup>3</sup> gave results which ran parallel with the clinical findings and the amounts of B<sub>1</sub> in the diet.

It is clear from this work that the position of vitamin B<sub>1</sub> as the antineuritic vitamin has been strongly assailed, supporting the sceptical view put forward by Meiklejohn<sup>4</sup> in 1940. He concluded his review with the statement that probably a multiple deficiency is responsible for nutritional neuritis but that there is still a possibility that the true antineuritic vitamin has yet to be discovered. By the use of crystalline vitamins Wintrobe and his colleagues have shown that neither riboflavin nor nicotinic acid has any effect in maintaining the integrity of nervous tissue.<sup>5</sup> It was then found that the ataxic gait and the degenerative nerve lesions brought about by a dietary deficiency of the vitamin-B complex are completely prevented by whole desiccated liver.<sup>6</sup> The anti-pernicious-anaemia fraction was found to be the most potent of the individual liver fractions, none of which are as efficacious as whole liver, even when given parenterally, and the results suggest that there is a need for passage of the nerve-protection factor through the gastro-intestinal tract. Finally it has been

<sup>1</sup> *J. Nutr.*, 1940, 20, 607.

<sup>2</sup> *Johns Hopk. Hosp. Bull.*, 1942, 71, 141.

<sup>3</sup> *Ibid.*, 1940, 67, 107.

<sup>4</sup> *New Engl. J. Med.*, 1940, 223, 265.

<sup>5</sup> *Johns Hopk. Hosp. Bull.*, 1943, 67, 377.

<sup>6</sup> *J. clin. Invest.*, 1942, 21, 71.

shown<sup>7</sup> that the dietary deficiency of either pyridoxine or pantothenic acid leads to an ataxic gait in swine and degeneration of sensory neurons which could invariably be prevented by the administration of these substances. The claim of one of these constituents of the vitamin-B complex is considerably strengthened by the finding that the protective actions of the various liver fractions is proportional to their contents of pantothenic acid.

### OESOPHAGEAL STRICTURE: A REMARKABLE CASE

It is not often that one finds excellent narrative, sustained interest, and valuable information in a medical article, but all these are in an account by Prof. Grey Turner<sup>8</sup> of the treatment of a case of fibrous stricture of the oesophagus in which normal swallowing was quickly restored by simple bouginage. For 19 years the patient had taken all his food by gastrostomy and had abandoned hope of any relief. The patient was a young medical man 26 years old, and himself contributes the case history, which is a model of what a case history should be. The stricture had followed the swallowing of caustic soda at the age of 7, and gastrostomy became necessary soon after. A year later he was taken to Copenhagen, where Prof. Rovsing found what was thought to be complete obliteration of the lumen of the oesophagus and attempted to perform an anterior oesophagoplasty by means of a skin tube. This failed completely, and after a stay of 18 months the patient returned home with a cervical fistula and a gastrostomy, which were eventually connected by a rubber tube through which he took all liquids and solids without disability for many years.

Eventually, while a medical student, the patient began to have severe pain of ulcer type which proved so disabling that he consulted Prof. Grey Turner. Radiographic examination revealed a long stricture in the oesophagus which was said to be absolute, but owing to Grey Turner's experience of similar unpromising cases in which treatment by bougies had proved successful<sup>9</sup> a further attempt at this was advised. The patient was enthusiastically co-operative, and there is no doubt that a great deal of the ultimate success was due to his intelligence, perseverance, and courage. After great difficulty a No. 6 oesophageal bougie engaged in the stricture and eventually was made to pass it; a week later the next larger size could be used. This simple statement hides much dogged endeavour on the part of the patient, who would spend an hour or more, often suffering much physical revulsion, before the passage could be achieved. Grey Turner emphasizes that it is not a question of "passing" or "forcing" the bougie through the stricture, for at no time could this be done by intent. The patient was merely assisted or himself assisted in the swallowing of the bougie. Rapid forcible dilatation of a stricture at intervals, especially under anaesthesia, is not good practice and leads to further damage by tearing scar tissue, which is then followed by more fibrosis and more contracture. The essence of treatment should be the gentle, daily, self-dilatation; the co-operation of the patient is imperative, and in a difficult case not even the greatest skill on the part of the surgeon can replace its absence.

It was soon possible to give some solid food, itself a great additional help, since each bolus acts as a dilator. From this time on progress was rapid—of course aided by the passage of increasing sizes of bougies—so that the patient was able to take all his food by mouth and was discharged from hospital exactly 60 days after admission. He had entered being unable to swallow even saliva by

the natural route, with disabling gastric pain from long wearing of the gastrostomy tube, and without apparent hope of relief from his stricture; and yet he left hospital after this relatively short time able to eat and swallow almost like a normal individual. Apart from minor setbacks his progress was maintained during the rest of his medical studies and even during the arduous duties of a house officer during heavy air raids. Eventually it became possible to close his gastrostomy and later still his cervical oesophagostomy. This was done over a year ago, since when he has served as house-surgeon to Prof. Grey Turner, working hard and successfully with no difficulty in swallowing.

The story of this simple but dramatically successful treatment for what had been thought to be an incurable condition makes most encouraging reading. Grey Turner emphasizes that even in a case with apparent complete fibrous obstruction a narrow, tortuous, but mucous-lined track may exist and may well be exploited to achieve success. It is especially important to bear this in mind in view of the recent accounts of routine anterior oesophagoplasty with jejunal tubes being performed for simple stricture of the gullet.

### OPERATION FOR PATENT DUCTUS

The surgical treatment of congenital patency of the ductus arteriosus has been to the fore in recent years. Examining the records of 57 adults who had had simple patency of the ductus arteriosus and had died, Keys and Shapiro<sup>1</sup> found the cause of death to be subacute bacterial endocarditis in over 40%; 28% died of congestion failure, and 3.3% from rupture of a pulmonary aneurysm. After the age of 17 years patency of the ductus arteriosus was associated with an average expectation of life of about 25 years, or about half that of the general population. These authors concluded that an attempt at ligation is justified in spite of the absence of signs of decreasing adjustment to the defect.

The surgical treatment of the infected ductus is, however, well established. Touroff<sup>2</sup> has operated on 12 cases: seven patients recovered, two died as the result of the operation, and three died of their disease in spite of surgical intervention. Tubbs<sup>3</sup> in this country operated on nine cases: five patients are well after 18 months (the longest after 3½ years), one after 4 months. One patient died from the operation, and the seventh patient, though alive when the paper was written, still had bacteraemia and was reckoned a failure. The combined figures give success in 13 cases out of 21 operated on, with 3 operation deaths. Touroff considers peripheral embolism a *contraindication* to operation when the vegetations have spread from the infected ductus to the mitral and aortic valves. Two of his cases with signs of peripheral embolism were unaffected by operation and continued to have bacteraemia after it. Spread of the infection to the aortic end of the ductus without signs of aortic valve disease will not respond satisfactorily, but it may be difficult to diagnose the condition unless peripheral embolism occurs. It is less certain what the result will be where there is spread of infection on to the pulmonary valve. Cardiac failure, however, and poor general physical condition are not considered to contraindicate operation. One case with pulmonary infarction recovered.

The operation usually consists of ligation of the ductus, though in two cases Touroff divided it. Many of the cases had preliminary chemotherapy without effect, and though it is probable that a short course of drug treatment is advisable, operation must not be too long delayed.

## THE LATE G. C. ANDERSON

## SERVICE OF REMEMBRANCE.

A memorial service for Dr. Anderson was held on the day of the funeral, Wednesday, Jan. 5, in St. Pancras Parish Church, which is close to the house of the British Medical Association. The large church was filled with personal friends and colleagues and representatives of Government Departments, medical bodies, and the many organizations with which the late Secretary in one capacity or another had been actively associated. Such an assembly, many of those present bearing names eminent in medicine and in public affairs, was an indication more significant than many words could have been of the esteem in which he was held and the impress of his personality and work. The principal Officers of the Association and members of Council living in or near London attended, and many members of the Association came from distant Divisions. All grades of the staff at headquarters, from whose building the flag was flying at half-mast, were present. The service preceded the funeral, which was private and took place at Golders Green Crematorium later in the day.

The Vicar of St. Pancras (the Rev. Frank Jones), whose helpfulness in facilitating the arrangements at short notice was greatly appreciated by the Association officials, conducted the service. He was assisted by Mr. Maurice Vinden at the organ. The choir of St. Mark's, North Audley Street, attended, and their lead in the singing of the hymns, "For all the saints," "O love that will not let me go," "The King of Love my Shepherd is," Blake's "Jerusalem," and the twenty-third Psalm, added greatly to the beauty of the service.

## Lord Dawson's Tribute

Dr. H. Guy Dain, Chairman of Council, read the lesson from Ecclesiasticus ("Let us now praise famous men"), and Viscount Dawson of Penn, the President of the Association, ascended the pulpit and paid a short but feeling tribute. "Gathered together at this service of remembrance for George Anderson," he said, "we sorrow for his death, but equally express our thankfulness and admiration for his life." He proceeded to sketch the salient facts of Dr. Anderson's career, pointing out what a background of varied experience in medical practice he had had before beginning his administrative office as Deputy Medical Secretary in 1919.

"His eleven years as Secretary of this great and expanding Association (its numbers nearly doubled during his term of office)," Lord Dawson continued, "coincided with the rising tide of new knowledge, with earnest endeavour to bring within the reach of all citizens services for the furtherance of health and the cure of disease, and widening interest in the health and welfare of the people. Then, as the darkness of war drew near, came his organization of recruitment of the whole profession for war conditions, and when war did come the bringing into action of that vast machinery of which he has been the moving spirit and ever-constant guardian. We may add to this his idea—for it was his—of the Medical Planning Commission, which resulted in a considerable consensus of opinion within the profession in the matter of medical reconstruction, now so imminent for public discussion.

"In the earlier years of his Secretaryship he showed his powers of organization in other fields by the visits of the Association over-seas—I may instance the World Tour and the memorable meeting at Melbourne in 1935. Not only was the organization perfect, but his genius for friendship brought men of different countries together and enhanced the reputation of Great Britain. These are but a few examples of his many activities, which during the war absorbed his laborious days; indeed, the later years of his career were the history of the Association.

"I pass to make reference to the attributes which, combined with his great gifts of organization, made Anderson such an outstanding success as a leader of men. His erect, active body, befitting the athletic prowess of his youth, made him an impressive figure. His charm of manner and his 'forthcomingness' drew men towards him, and his genius for fellowship made the world his parish. Faith and foresight inspired his thought; his power of concentration, his prodigious capacity for work, and his infective enthusiasm got things done.

"In discussion he was receptive, and in speech firm and persuasive, and his gaiety of spirit was seldom far away if proceedings dragged and men were dour. In the course of his work he lit many fires in cold rooms. In conferences and negotiations with Government or other bodies his intimate knowledge of the subject, his judgment, and the complete trust reposed in him made him a strong and welcome representative.

"Anderson's many gifts of mind have been the instruments of his success, but these were not the source of the warmth of regard and affection which he aroused wherever he went and will make his memory long abiding. Underneath all, he loved his neighbour as himself. There was always in his mind a desire to be helpful to his fellows and, forgetting self, to do his all for his day and generation. 'He was a good man and did good things.'

Here our thoughts turn to the partner of his life and his doings, who encouraged his aspirations and shared his struggles, his triumphs, and his trials. To her our hearts extend affectionate understanding. Those who worked with Anderson will profit by what he has so richly garnered, and still more by his high example. We bid him farewell and shall hold his memory in our hearts."

After the Blessing the Vicar read the concluding passage from the second part of *The Pilgrim's Progress*, the story of how Greatheart passed over, and "all the trumpets sounded for him on the other side." This was followed by Jeremiah Clarke's trumpet voluntary, orchestrated by Purcell, and the triumphant tones of Chopin's "Funeral March" brought the service to a close.

## The Congregation in St. Pancras Church

Those present at the service included the following:

Representing the British Medical Association: Lord Dawson (President), Dr. H. Guy Dain (Chairman of Council), Sir Kaye Le Fleming and Mr. H. S. Scuttar (Past Chairmen), Dr. J. W. Bone (Treasurer), Dr. O. C. Carner, Mr. Zachary Cope, Dr. F. Gray, Dr. E. A. Gress, Col. H. A. Proctor, and Dr. S. Wand (members of Council), Sir Farquhar Buzzard (former President), Dr. C. O. Hawthorne (former Chairman of Representative Body), and the following among other representatives of Divisions: Dr. G. E. Orme (Westminster and Holborn), Dr. A. Baldie (Marylebone), Dr. H. S. Pasmore (Kensington), Dr. A. T. Rogers (Bromley), Dr. A. P. Ford (East Herts), Capt. Laurie Smith (Blackpool); also the Officials of the Association, the Solicitor, and many members of the staff at B.M.A. House from all the departments. Severe illness prevented Dr. Alfred Cox from attending.

The Ministry of Health was represented by Sir John Maude (Secretary), Sir Wilson Jameson (Chief Medical Officer), Prof. F. R. Fraser (Director-General, E.M.S.), Sir Weldon Dalrymple-Champneys (Deputy Chief Medical Officer), Dr. F. Murchie, and Mr. A. W. Neville (Principal Assistant Secretaries). Other representatives of Government Departments were: Dr. J. Alison Glyke (Board of Education), Dr. E. R. A. Merewether and Mr. R. W. Luce (Ministry of Labour and National Service), Dr. A. G. H. Smart (Colonial Office), Dr. A. Sandison (Ministry of Pensions), Mr. R. B. Crabb (Ministry of Fuel and Power), Lieut.-Gen. Sir Alexander Hood, Director-General, represented the Army Medical Services, and Mr. Louis Infield represented Sir Geoffrey Shakespear and the Medical Personnel (Priority) Committee.

The Royal College of Physicians was represented by Prof. F. S. Lanzmead and Dr. H. E. A. Boldere (Registrar), and the Royal College of Surgeons by its President (Sir Alfred Webb-Johnson), Surgeon Rear-Admiral Gordon-Taylor, and Sir Hugh Lell. The following bodies were represented by their Presidents: the Royal College of Obstetricians and Gynaecologists (Mr. Eardley Holland) and the Royal Society of Medicine (Sir Henry Tidy), and the Society of Apothecaries by its Master (Sir Stanley Woodward). Other representatives of medical bodies were Sir Edward Mellanby (Medical Research Council), Dr. A. Hope Gosse (Medical Society of London), Dr. Janet Aitken (Medical Women's Federation), Dr. J. C. Bridge (Association of Industrial Medical Officers), Dr. E. Goodwin Rawlinson (Royal Institute of Public Health and Hygiene), Dr. Alan Moncrieff (British Paediatric Association), Dr. Charles Newman (British Postgraduate Medical School), Major H. Leekwood Stevens (London School of Hygiene and Tropical Medicine).

Others who were present were the Viscountess Dawson of Penn, Lady Moran, Dame Louise Mellroy, Sir Henry Dale, P.R.S., Prof. T. B. Johnston, Mr. W. McAdam Eccles (also representing the British Social Hygiene Council), Mr. James Wyatt, Miss Elizabeth Bolton (London School of Medicine for Women), Sir T. P. Dunhill, Sir Arnold Lawson, Brigadier J. R. Rees, Col. C. B. Heald, Sir Robert Stanton Woods, Prof. J. R. Larnmonth, Capt. G. S. Ellison, M.P., Alderman Sir David Davies, Surgeon Rear-Admiral Malone, Dr. H. Crichton-Miller, Dr. Andrew Topping (London County Council), Dr. S. C. Acock (Reading), Dr. G. Clark Trotter (Hampstead), Mrs. Scott (representing Dr. C. F. T. Scott, Willstead), Dr. Arthur Ricketts, Miss C. Neill (representing Lady Neill), Mr. H. L. Jackson (H. K. Lewis and Co., Ltd.), Dr. Lina Potter, Dr. Margaret Jackson (Lancet).

Representatives of various medical and ancillary organizations included Dr. J. B. Mennell (Association of Anaesthetists), Dr. J. R. Whitwell (Royal Medico-Psychological Association), Dr. Harley Williams (National Association for the Prevention of Tuberculosis), Capt. E. J. C. Chapman (British Empire Cancer Campaign), Dr. R. Sutherland (Central Council for Health Education), Dr. Robert Forbes (Medical Defence Union), Dr. C. L. Battison (London Panel Committee), Dr. L. G. Glover and Mr. E. C. Pennefather (Royal Medical Benevolent Fund), with Lady Woodward representing the Ladies Guild.

Miss Macfie (Royal College of Nursing), Mr. H. N. Linstead, M.P. (Pharmaceutical Society of Great Britain), Mr. T. Heselthine and Mr. G. A. Mallinson (National Pharmaceutical Union), Mr. Donald Cox and Mr. W. G. Senior (British Dental Association), Mr. Horace H. Rew (Examining Board for England), Prof. Samson Wright and Mrs. Haigh (Central Office for Refugees), Mr. P. W. L. Camps (British Hospitals Association).

Other bodies represented were: London Insurance Committee, National Association of Insurance Committees, National Association of Clerks to Insurance Committees, National Amalgamated Approved Society, Joint Committee of Approved Societies, National Federation of Employees Approved Societies, National Ophthalmic Treatment Board, Guild of British Dispensing Opticians, King Edward's Hospital Fund for London, Hospital Saving Association, British Hospitals Contributory Schemes Association, War Organization of British Red Cross and Order of St. John, Industrial Welfare Society, Clerical, Medical, and General Life Assurance Society, Medical Sickness, Annuity, and Life Assurance Society, Medical Insurance Agency, British Medical Bureau, Public Dental Services Association, Chartered Society of Physiotherapy, and the Magistrates Association. Also represented were the Sandy Lodge Golf Club and the Rotary International.

### FURTHER TRIBUTES

The following further appreciations of Dr. Anderson have been received, supplementing those written by Sir Kaye Le Fleming, Mr. H. S. Souttar, and Dr. H. Guy Dain, and published in last week's *Journal*:

Lord MORAN, President of the Royal College of Physicians, writes:

The loss of a man like Anderson, who had worked at the headquarters of the British Medical Association for a quarter of a century, would be felt by the profession at any time; just now it is nearly irreparable. Others are more competent to record what he did for the Association, but I want to say something of the work of the Association for the nation. It planned for war in peace, when foresight was not common. The register of doctors, which Anderson designed, made it possible when war came to preserve a just balance between the demands of the Services and of the home front. For he was a realist. He knew what the average doctor was thinking, what he would accept and what he would not, and this knowledge gave him poise and lent weight to his word in council. He had the independence of his race, and the down-right honesty of his speech was the expression of a mind that had not been touched by the blight of routine. He could see, beyond the interests of the members of the Association, what was good for the country as a whole. When he had to say things that were unpalatable, he said them to your face, disarming criticism, so that when I came to propose his election to the Fellowship of the Royal College of Physicians, at a time when the policy of the College and that of the Association were sometimes at variance, it was typical of the man that there was no opposition of any kind to his election.

In his youth there was a time when no Scot could live with him over hurdles, and he kept to the end the easy way with men which often has a beginning in the good fellowship of sport.

Anderson felt the burden that presses on those who have to make decisions on matters of moment for others, but he found comfort always where alone it can be found: in the integrity of his own mind and in the quiet peace of his home.

Prof. R. J. A. BERRY writes:

As a member of Council who has probably known personally the late Dr. G. C. Anderson for a longer period of time than any of my colleagues it seems fitting that I should assume the privilege of a friend to say a few words of farewell.

In those now distant days when the intelligentsia of the period were fond of describing the times in which they lived as *fin de siècle*, and the less intelligent were vehemently arguing whether the year 1900 was the last of the nineteenth century or the first of the twentieth, there walked into my retiring room at the anatomy department of the New School of Medicine of the Royal Colleges of Edinburgh a tall gracefully built youth who expressed his desire of joining the anatomy classes then under my charge. A student of the University of Edinburgh, he gave his name as George Cranston Anderson. From that moment there was born between us a firm personal friendship which only terminated on Jan. 1, 1944. In those days the association between teacher and taught was more close, intimate, and personal than it is to-day, and on the whole I think the loss is the teacher's. With Anderson's graduation, his departure to the kingdom of Fife,

and my own parting from the city of our dreams, our ways in life were naturally sundered but never dissolved. Always, on returning from over-seas to London, one of the pleasures was a call upon George. Here was conviction, if indeed conviction were needed, that in him, as revealed by his talk, the Association had secured the aid of a loyal, devoted, and enthusiastic servant. Confronted as he constantly was by a multitude of diverse minds, never once did I hear him speak unkindly of those from whom his duties sometimes compelled him to differ.

Recently at Manchester, and for the last time, I heard Anderson address an enormous congregation of medical men, not all of whom were at one with him. Nevertheless Anderson's tact, his courtesy, his powers of explanation, his mastery of his subject, and an all-pervading good humour, afforded a most convincing proof of his devotion to his colleagues and the best interests of the Association he was so proud to serve. "Evolution, not revolution," and never did Anderson plead more convincingly or with greater effect. "Let us have faith that right makes might; and in that faith let us, to the end, dare to do our duty as we understand it," and George Cranston Anderson did it to the very end.

Lieut.-General Sir JAMES A. HARTIGAN, K.C.B., writes:

Will you allow me to express my very real regret at the death of Dr. Anderson? During the four years I was at the War Office I was in close touch with him, and learned to appreciate his clear and active mind, his powers of administration, and his far-seeing vision. I would say that his main aims in life were to do all in his power to provide the best medical care for the community at large, and to further the interests and prestige of his profession. He was very quick at reaching the kernel of a problem, however complicated, and he always expressed his views with admirable clearness and brevity. To any scheme which had for its object the advancement of the medical branches of the Defence Services he gave his whole-hearted support. He possessed many statesmanlike qualities, and during the years to which I refer had a more lively appreciation of the dangerous position of his country than was usually held at that time. I used to think that he would make an excellent Member of Parliament. He was delightful to work with, and I retain very pleasant memories of my association with him. His passing at this time is a grievous loss to the profession.

### THE FIGHT AGAINST RHEUMATISM

The seventh completed year of the Empire Rheumatism Council is the subject of a report by Lord Horder, its chairman, who comments upon the reduction in the annual number of deaths from acute rheumatism (which may be taken as largely synonymous with juvenile rheumatism) in England and Wales during the five-year period 1938-42. The number fell by almost exactly 50%. Corroborative evidence of the gradual conquest of this form of rheumatism is forthcoming from the Council's Research Foundation, which shows that the incidence of acute rheumatism among a large number of youths has steadily declined during recent years. This decline coincides with an increasing measure of effective control and treatment so far as the child is concerned. On the other hand, for adult rheumatism the means of effective treatment have been available for only a small percentage of sufferers, and here there is no evidence of decrease. The treatment centres report great increases in the number of patients seeking treatment; in one London hospital the number treated in 1943 was almost double that for 1942.

#### Clinical and Laboratory Investigations

The Council, in spite of obvious wartime difficulties, manages to keep going a considerable amount of research, both laboratory and clinical. The laboratory work has included flocculation tests of an antibody in certain rheumatic sera and antihistase titration and serum treatment, and the clinical research a study of the value and correct dosage of gold salts in the treatment of some forms of rheumatic disease, and into the efficacy of an enzyme preparation. Attention is drawn to the great difficulty in carrying clinical investigations to conclusive results owing to the lack of centres at which tests can be done under adequate control conditions among

considerable groups of patients for a sufficient length of time. It is hoped that the promised post-war development of national health services will remedy this. The Council is expecting shortly to have direct discussion with the Minister of Health concerning the assurance given more than two years ago of the Government's intention in its national health policy to ensure that everyone will receive treatment appropriate to his needs. Mention is made of a report from Moscow of a discovery by Bogolometz, of the Russian Academy, of a serum which is claimed to have definite effects in the treatment of arthritic conditions arising from rheumatic disease. Lord Horder has communicated with this Russian scientist asking for further particulars, and inquiring whether it is possible to send a supply of the serum for test.

## NEW YEAR HONOURS

The names of the following members of the medical profession were included in the final section of the New Year Honours List published in the *London Gazette* of Jan. 4:

### O.B.E. (Civil Division)

THOMAS RICHARD WEBSTER ATKINS, L.R.C.P.S. Ed. Ship Surgeon, Merchant Navy.

FRANK SEBASTIAN COCKSEY, M.D. Medical Officer of the Rehabilitation Department, Horton Emergency Hospital.

GEORGE MACFAR, M.B., C.M. For public services in Lanarkshire.

JOHN CHANCELLOR MCKENZIE, M.B., Ch.B., J.P. Commissioner of Medical Services, Scotland Region, Ministry of Pensions.

EDWARD LOGGIE MIDDLTON, M.D., D.P.H., H.M. Medical Inspector of Factories, Ministry of Labour and National Service.

WILLIAM JOHN RICHARD, M.B., C.M., F.R.C.P.S. Medical Superintendent, Emergency Hospital, Law Junction, Lanarkshire.

JANET MARIA VAUGHAN, D.M., F.R.C.P. Organizer of the Royal Naval Blood Transfusion Service Centre.

MRS. MARTHA ISABEL GARVICI, M.B.E. Senior Lady Medical Officer, Egyptian Ministry of Education.

### M.B.E. (Civil Division)

MRS. HARRIET MINNIE LÉVICK, M.D. County Borough Organizer, Middlesbrough, Women's Voluntary Services for Civil Defence.

GERALD EARL THORNTON, M.B., B.Ch. Chairman, Air Training Corps Local Committee, Salisbury.

## TRELOAR CRIPPLES' HOSPITAL

It is hard to realize that it is 35 years since Sir William Trelor at the London Mansion House planned what is now called Lord Mayor Trelor Cripples' Hospital and College (the college is for training boys in various trades) under the medical superintendency of Sir Henry Gauvain. At first cases of non-pulmonary tuberculosis were received at Alton, and afterwards the benefits of the hospital came to be extended to all the crippling diseases of childhood. Portsmouth was the area which benefited first, then the whole of Hampshire and the Isle of Wight, and now patients are taken from any part of the country or the Empire, though, of course, the after-care of distant patients has to be delegated to others. The help of the plastic surgeon has been increasingly invoked, first to treat facial disfigurements the results of lupus vulgaris, then all kinds of congenital or acquired deformities or deviations affecting the appearance. The latest medical report states that during the year 112 plastic cases were admitted and underwent 163 successful operations. The applications for admission for cases of tuberculosis of the bones and joints are rapidly diminishing—for example, the percentage of admissions for tuberculous disease of the spine, which was 40 in 1912, was down to 3.6 in 1942. Of the other cases admitted during the year under review 234 were of an orthopaedic character. About 1,500 splints and surgical appliances were made and repaired in the splint shop, and nearly 7,000 treatments were given in the light department. Out-patient clinics are held regularly in 14 towns within reasonable distance of Alton.

Continuing its practice of issuing small, neat, but comprehensive leaflets of advice on health matters, the Central Council for Health Education has chosen the title "Right Dress for Health" for a most useful one on the way to dress in differing temperatures. "Just Nerves" is a good title for advice to the "worriers" of this world, while "War on Disease," as its name suggests, covers infectious diseases generally. All these leaflets, as well as one on "How to Avoid Influenza," may be obtained from the offices of the Central Council, Tavistock House, Tavistock Square, W.C.1.

## Correspondence

### Consultant and Specialist Services

SIR.—In March, 1943, at the invitation of the Minister of Health, the Royal Colleges combined with the British Medical Association and other bodies to form a Representative Committee in order to discuss with the Minister the formation of a comprehensive medical service. Apart from the common duty of planning this service for the country, the Colleges have a particular responsibility in regard to the consultant and specialist services, and we think it right to explain what we have done to discharge that responsibility.

In the first place, when the Standing Joint Committee of the three Royal Colleges requires information and advice in matters concerning the special branches of medicine and surgery it refers to the official bodies representing those branches.

The College members of the Representative Committee are briefed and advised by an existing committee of the Colleges. This committee consists of: (1) 13 representatives of the Royal Colleges; (2) 2 representatives nominated by the teaching hospitals of each University in England, Wales, and Northern Ireland; (3) 11 representatives from the non-teaching hospitals; (4) 1 representative from each of the specialties.

This committee, apart from its representative character, provides machinery for referring questions to its constituent bodies—an essential provision, in our judgment, of any committee which sets out to give advice on such important matters as terms and conditions of service. By these means the Colleges hope to keep in touch with the views of consultants and specialists throughout the country, so that they may give effect to them in any action they may take.

The Colleges have also taken steps to ascertain what consultants and specialists are available at the present time. It is clear that the Minister of Health must know how many consultants there are and where they are available, and he is having a survey made under the direct auspices of the Royal Colleges, who are acting in this matter in co-operation with the Universities and representatives of the British Medical Association. The result of this survey will not be published; it is for the personal guidance of the Minister.

Previously, the Colleges had laid down certain standards which they thought should be required of any practitioner who wished to become a consultant in the future. These criteria are not meant to be retrospective. They will only affect those taking up consultant work in time to come. The only criterion required now is that a man is accepted as a consultant by the practitioners in his neighbourhood. Each district is therefore being asked to supply the necessary information.

In our view, the services of every consultant who is now recognized as such by the profession in his neighbourhood will be needed in any consultant service that may be set up after the war. We think it probable that provision may be made which will enable practitioners who hitherto have not been exclusively engaged in consulting practice to devote themselves solely to consulting work.—We are, etc.,

MORAN,

President of the Royal College of Physicians.

ALFRED WEBB-JOHNSON,

President of the Royal College of Surgeons.

EARLDY HOLLAND,

President of the Royal College of Obstetricians and Gynaecologists.

London.

\*\* It is useful to recall in this connexion the procedure which the B.M.A. has decided to follow in order to ascertain and express the views of the profession as a whole on the White Paper. It was described in the *Supplement* of Jan. 1, and is summarized under "Future Procedure" in an important letter sent to all practitioners serving over-seas and to all medical prisoners of war. This letter is reproduced in full in the *Supplement* this week. It will be seen that the proposed procedure includes the issue of a questionnaire, prepared by an independent expert body, to every member of the profession

at home or abroad, whether member or non-member of the Association. The whole question of the machinery for establishing a consultants list or lists is now under consideration by the B.M.A., and in due course a statement will be made. —Ed., *B.M.J.*

### The Prisoner-of-War Mentality

SIR,—I have read, as thousands of others have read, Major P. H. Newman's human and thoughtful article (Jan. 1, p. 8), and it assuredly must have set many heart-cords in vibration. Masterly though his impressions are, they give but part of the picture which is yet to be revealed to us, for I assume he has no experience beyond the prisoner-of-war mentality in respect of Europe.

As no Service prisoners of war have been exchanged by the Japanese, and as only a mere handful have escaped (and so far as I know none of these were doctors), we still have yet to learn how the 130,000 prisoners and internees stood up in the three stages outlined and how they will react in Stage IV—the repatriation period. It is the "lengthy period of boredom," already amounting to two unrelieved years, which must leave its permanent marks on these men and women, for the Japanese have studied how best to inflict mental anguish on their captives as opposed to the physical atrocities described in the House of Commons and elsewhere, and such anguish dates right from the "breaking-in period" and must accentuate mental symptoms; witness their refusal to allow International Red Cross delegates to visit camps, their refusal to accept parcels, comforts, and medical supplies, their holding back of some quarter of a million letters from relatives to prisoners, their refusal to recognize any messages to prisoners other than twenty-five words on a card at monthly intervals, and so on, all of these inflictions costing the captors nothing but meaning so much to the mentality of the prisoner. These are very, very slow wearing-down cruelties, the relief of which can result in no "acute emotional reaction" but a chronic psychological stigma.

On Jan. 1, 1944, a card was received from a prisoner of war, Hong Kong, in which he states that no educational facilities are allowed; most of the time was spent in playing chess, presumably with home-made pieces. It is significant that this and many other cards in this recent batch bear no dates; in any event such news as comes or goes is well over six months old—another cheap and studied way to promote anxiety.

There is only one class of man or woman who can experience all this (and much more) and who can be rehabilitated to fit into normal reconstructed society again—and that is the "superman." The remainder will be a problem for their lifetime.

The suggestion for an organization for the aid of returned prisoners of war is an admirable one; indeed, such a formation will probably be essential; but it is doubtful whether it is desirable to form yet another body. The Government Departments—Navy, Army, Air Force, and others—cannot do these men ashore, demobilize them, and so wash their hands of it all. Such a mechanism surely exists in the War Organization of the British Red Cross Society and Order of St. John of Jerusalem, for which body our prisoners have the highest regard and affection, and to whom they and their relatives would naturally turn for any subsequent assistance. The medical personnel, particularly on its psychological side, may need amending for this purpose, but there are offices already in all large towns—e.g., over 100,000 population—and smaller, and, moreover, the organization is world-wide.

But before any of this can be arranged we still have to wait and see what these Asiatic barbarians will do to our prisoners as the war progresses.—I am, etc.,

Pells Wood, Kent.

B. RICHARDSON BILLINGS.

### School Medical Service

SIR,—Ever since the inauguration of the School Medical Service school medical officers have frequently drawn attention to the verminous conditions so prevalent among large numbers of the children attending the public elementary schools. Though public opinion was scarcely affected by such reports it was exceedingly stirred as a result of the publicity given to these

matters following the Government's evacuation scheme. The Ministry of Health and the Board of Education then addressed special memoranda to local authorities on the matter, and authorized the appointment of additional staff in an endeavour to cope with the situation. The cumbersome Seabies Order was also issued (under the Defence of the Realm Regulations) to strengthen the hands of those who had to deal with the unwholesome conditions. In view of these circumstances it is surprising to find that Section 52 of the Education Bill, if allowed to become law, will seriously curtail the existing powers of school medical officers and nurses and transfer them to the head teachers, who are to be judges, juries, and appellates. If this reactionary section is not drastically amended an absurd position will arise whereby regular cleanliness surveys by the school nurses will no longer be possible. In consequence of this many primary-school children with negligent parents will almost certainly revert to that disgraceful condition so frequently met with in the first few years after the inception of the School Medical Service.—I am, etc.,

Liverpool.

R. GAMLIN.

### Actiology of Sciatic Pain

SIR,—It would be a sad thing for the many sufferers from sciatic pain in this country if their doctors took notice of the so-called "rational" treatment advised by Sir Arthur Hurst (Dec. 18, p. 773). They would have to be told first that their pain was imagined; secondly, that the only thing for it if they persisted in believing in its existence was prolonged rest in bed perhaps with their hips and affected limb encased in plaster-of-Paris; and, thirdly, that if they still complained of pain they would be handed over to a neurosurgeon to have a severe operation on the spine for removal of a node on an intervertebral disk. It is perhaps useful to "debunk," as Sir Arthur Hurst does, the treatments of the past—notably introduced, as it happened, mainly by physicians. It is another and quite unjustifiable thing to state a treatment having, except in one part, no apparent rational basis whatever.

There is no more important subject in medicine to-day than backache with associated pain in the limbs, because of the amount of disablement and loss of work it entails. It is absurd and unkind to brush it aside as hysterical. Mainly through the work of orthopaedic surgeons and of some radiologists and pathologists, a great deal more is known about this subject now than formerly. It is certain that there are a number of physical causes which can be readily determined by thorough examination, and that pure hysteria and malingering are rare. In 20 years of orthopaedic practice I have dealt with an estimated 7,000 cases of backache with or without radiating pain, and for the last 10 years have treated not fewer than 500 to 600 a year. I have rarely seen a case without a physical basis for the symptoms, though, as in all clinical states, the reaction of patients to pain varies, and there is in many cases an associated psychological factor.

It is a pity to find the term "sciatica" still being used in your Journal. It is in use by the public to describe any pain in the leg (and even elsewhere!) and many doctors are nearly as vague. Sciatic pain is felt only in the buttock, outer and/or posterior aspect of the thigh and calf, and outer side of the foot. Sufficient is known now of the causes of pain in this distribution to make it as unjustifiable to use the term "sciatica" as if it were a single disease as to speak of abdominal pain instead of the different lesions which may be manifested by such pain. It is clear that sciatic pain may arise either (1) from an inflammatory or traumatic lesion of the fibrous tissue of the ligaments or fasciae in the lumbo-sacral and gluteal regions, or (2) from irritation of the roots of the lumbo-sacral plexus. The former includes fibrositis with or without localized tender points and fibrosis of ligaments following sprain or associated with disease of the bones or joints. Fibrositis may be doubtful in its actiology and pathology, but there is no doubt that it is a definite physical disorder. Chronic sprain in the lower back may be caused by accidental injury, persistent occupational strain, or strain from deformity—postural, congenital, or due to neoplastic, tuberculous, or other disease—or to degeneration of the intervertebral disks. The various states included in this category, especially fibrositis and osteo-arthritis without or with degeneration of the disks (spondylosis deformans), are certainly the most common causes

of low back and sciatic pain, as they are of similar pain at higher levels of the trunk and in the neck and upper limbs. The distinguishing character of sciatic and other radiating pain from these lesions is that it is purely "referred," not accompanied by objective neurological signs, though there may be subjective symptoms. Appropriate orthopaedic treatment, after determination and elimination when possible of aetiological factors such as focal sepsis, gives relief of pain in most cases.

Sciatic pain is far less often due to irritation of the roots or trunks of the lumbosacral plexus. Such irritation may arise from a rupture into the vertebral canal of the intervertebral disk between the fourth and fifth lumbar or the fifth lumbar and first sacral vertebrae, or from perineuritis, as well as from rarer lesions such as neoplasms and arachnoiditis. I believe that posterior disk rupture is not so common as some enthusiasts consider, and that there is a danger of many spines being operated upon unnecessarily if cases of persistent sciatic pain are thought to be only neurosurgical, and if reliance in diagnosis is placed only on neurological signs. Having made, as a B.M.A. Research grantee, between 1926 and 1931 a study of the intervertebral disks and of the work of the few others in the world interested in the subject at that time, I have since then been on the look-out for cases of posterior disk rupture. Yet between July, 1937, when I diagnosed and treated perhaps the first case operated upon in this country, and the present time I had only 20 certain cases of this lesion (including one in the cervical and one in the thoracic region) out of some 4,000 cases of backache with or without radiating pain—that is, 0.5%. Considering only cases with sciatic pain, the incidence of disk rupture would, of course, be higher, but probably not more than 2% of all such cases. Disk rupture is scarcely to be considered as a possible cause of pain of recent onset in patients over the age of 40 years, as by then the disks have become too fibrous to be ruptured. Between the ages of 20 and 30, when the disks are highly elastic and still have soft centres but the spine has not quite the same resilience to trauma as in earlier years, is the period when disk rupture and the pain it may cause are most likely to occur.

Perineuritis of the sciatic nerve roots—so-called true sciatica—may never have been demonstrated, but I believe that it does occur, though it is certainly one of the less common causes of sciatic pain. By sciatic perineuritis I understand a condition with an identical clinical picture to posterior disk rupture but distinguishable from it. Both show, in addition to the typical pain in the limb, impaired or absent sensibility to pain and touch in the same distribution to a greater or less extent, diminished or absent ankle-jerk, and deviation of the trunk to the affected side in all positions or at least in bending forward when standing. In my observation these are the only states of sciatic pain which give pain in the leg on straight leg raising: in sacro-iliac lesions the pain is localized to over the sacro-iliac joint; in fibrositis and sprain in the gluteal or lumbar region it is also localized and corresponds with the tender points; other causes of sciatic pain do not give this sign at all. Myelography with iodized oil is the only positive way of distinguishing between perineuritis and disk rupture, as it shows up the rupture, but it is not infallible and should probably in any case be followed by laminectomy, as the oil may cause arachnoiditis if left in. For this reason it should be the last means of diagnosis after all causes of pain other than disk rupture have been eliminated. Another way of distinguishing between these two states is by epidural injection of local anaesthetic in saline into the sacral canal. The symptoms of many cases of perineuritis will disappear spontaneously with the elimination of remote focal sepsis. If they persist, epidural injection is usually effective immediately and permanently, but it has no effect in cases of disk rupture. I have made this injection in many cases and am sure that it effects a not merely psychological. It is not certain how it acts any more than it is clear how other medical empirical treatments of proved efficacy act.

Of course there is often a psychological factor in sciatic pain, but it is no more significant in such cases than in other clinical states. To maintain that it is the chief or only factor is an attitude of despair—or of vain hope—towards an important cause of suffering and disablement. To put patients to bed without an exact diagnosis may by chance relieve the

pain of a few, but for most wastes time and money and impairs the prospect of obtaining lasting relief by thorough investigation and treatment.—I am, etc.,

Bournemouth.

N. ROSS SMITH.

### Sciatica

SIR.—Sir Arthur Hurst, in his masterly survey of sciatica (Dec. 18, p. 773), appeared to establish the existence of a hysterical background—i.e., a psychological factor in the cause of the disorder—but in his remarks on treatment he entirely ignored any psychological approach to this factor. Physical trauma or exposure to the elements were assumed to be the cause of this admittedly semi-hysterical disease, and the psychological aspect was dealt with by forms of suggestion, more or less drastic, and directed towards the developed condition rather than towards a possible psychological cause.

The trauma complained of by the sciatica patient is reminiscent of the individual who contracted gonorrhoea by "straining himself," and the exposure, usually an imaginary draught, is similar to that blamed for the onset of facial neuralgia. An incontrovertible, severe, physical catastrophe—such as the kick of a horse, a fall from a two-story building, or a night spent lost on a mountain—rarely precedes either disease.

Those of us who have acquired a psychosomatic outlook believe that not only is the discovery of infidelity in a wife or the fear of impending bankruptcy more potent to lead us to becoming generally "run down" than excessive physical exercise, but that particular forms of mental strain and emotion appear to cause stress on specific parts of the organism, and result in definite types of disease or disorder. Treatment then indicates investigation with a view to unveiling: "What did he experience just before he took sciatica, and what emotions did he feel?" While it is true that a happening sufficiently severe to cause physical illness is invariably repressed and positive transference must be established to find it, the quest does not demand forty séances. It is often possible to reveal the upset and discuss the patient's future adjustment to it, all inside half an hour, especially if one has some knowledge of the emotion associated with the disorder under consideration.

A.B., an actor, comes home from tour to find his wife leaving the house with another man (on her way to take up residence with him) and taking her three children with her. Within a few days A.B. has pain extending from the left hip to the great toe. Two weeks later he is sent to hospital, where he receives treatment covering a wide range. He remains off work for five months, and in the course of the following six years has many recurrences, being off work in all nearly eighteen months. Superficial analysis of his thoughts and emotions: "The foundation of his life was no longer secure; deprivation of loved persons; loss of self-respect; desire to strike back." The experiences of patients just preceding the first attack of sciatica may be of infinite variety, but the emotions and feelings are of the same order. Permanent cure follows the regaining of solid ground under his feet with capacity for adjustment to his future.—I am, etc.,

Glasgow.

G. GLADSTONE ROBERTSON.

### The Cardiac Index

SIR.—Mr. Harold Dodd in his paper on the cardiac index (Dec. 25, p. 811) remarks that "it is seldom taught, and, because of this, when it is mentioned it meets with some scepticism." What this index represents is not clear; empirically it is stated that values above 100% and below 25% make the patient a poor surgical risk. "Abdominal distension, chestiness, pulmonary embolism, delirium, strange moods of manner, or sepsis" are given as post-operative sequelae of a too low or too high cardiac index.

To quote his example: "In elderly people the blood pressure is often around 140/70, giving a cardiac index of 100%" (i.e., abnormal and a contraindication to operation). Such a pressure is, of course, perfectly normal in an elderly patient; but he goes on to say that "pre-operative rest in bed for one, two, or three weeks, with a fluid intake of 6 to 8 pints daily and cardiac tonics, approximates these figures to, say, 130/80." It is well known that variations of ten points either

way may occur from day to day and from observer to observer: certainly such changes of themselves could not be taken to indicate any alteration in the efficiency of the cardiovascular system. What cardiac tonics are used? And what are "gentle" cardiac tonics? Why 6 to 8 pints of fluid a day? It is difficult to understand how such quantities of fluids are going to benefit a patient with fibrillation, as restriction of fluid is one of the standbys of treatment of the failing heart. Clinical details are not given, but if these patients were not in failure, then cardiac tonics and excess fluid do not seem to have been indicated for patients where fibrillation was apparently paroxysmal. In any case I imagine that different observers would arrive at widely varying cardiac indices when confronted with a fibrillating heart.

The statement that "the blood-pressure figures in themselves mean little" is most disturbing. A simple example will indicate the danger of such an assumption. A patient might be in marked left ventricular failure with a blood pressure of 200/140. This would give, according to definition, a cardiac index of 43%, which indicates a "fair surgical risk." Were the cardiac index to be generally adopted as an important criterion of operative risk—and, as Mr. Dodd makes little mention of other findings in his patients, one assumes that he attaches great importance to it—one hesitates to think of the large number of patients denied operation when urgently needed, and the equally large number who would be operated on when in no fit state.—I am, etc.,

Botleys Park, Surrey.

G. R. FEARNLEY.

#### Blood Pressure in Surgery

SIR,—All anaesthetists will agree with Mr. Harold Dodd (Dec. 25, p. 811) in stressing the importance of continuous blood-pressure and pulse-rate recordings during major operations. It is hoped that the combined anaesthetic charts and record cards designed by Dr. M. D. Nosworthy and now being tried out in many hospitals will soon become universally used.

Mr. Dodd places considerable reliance on the "Moots-McKesson cardiac index," saying that if it is below 33% or over 85% the post-operative outlook is poor. Unfortunately anaesthetists generally have been unable to place much confidence in any of the usual cardiac efficiency tests, such as those of Barach, Crampton, Moots, and Sebrasez. The Crampton test would seem to be the most scientific and has been adopted by the Athletic Association of America. It is not, however, applicable to bedridden patients. Dr. W. S. Sykes made an investigation of Barach's and Moots's tests in patients dying from cardiac failure in the medical wards of a large hospital. In no less than 62% of tests the results were misleading, one patient being deemed "operable" by both formulae 15 minutes before death. Might I suggest, therefore, that it is unwise to put these so-called tests and indices before clinical observation and experience.

It is not always realized that there is no such thing as a patient who is "so ill that he cannot stand the anaesthetic." Any patient with cardiac failure who is not *in articulo mortis* will improve temporarily under an inhalation anaesthesia, which begins with 100% oxygen in a closed circuit to which the anaesthetic agent is gradually added in minimal dosage. The question which so often faces the modern anaesthetist is not "Can this patient survive my anaesthetic?" but "Can I improve his general condition sufficiently to enable him to withstand the surgical trauma and to live long enough to benefit by the effects of the operation?" If the answer is not a reasonably certain "Yes," surgical interference is surely unjustifiable.—I am, etc.,

St. Albans, Herts.

C. LANGTON HEWER.

#### The "Surgical" Heart

SIR,—In his article in your issue of Dec. 25 Mr. Harold Dodd states that the Moots-McKesson "cardiac index" meets with some scepticism because it is seldom taught. It seems possible, however, that its unpopularity is based on a natural distrust of any formula which seeks to reduce a complicated problem to a simple rule-of-thumb. Measurement of the arterial blood pressure cannot reasonably be expected to replace the need for an accurate cardiac diagnosis, even for surgical purposes.

It is common to find a normal cardiac index although gross cardiovascular disease is present; this is so in many cases of coronary arterial disease (including not a few cases of recent coronary thrombosis), in most mitral lesions, in cardio-aortic syphilis without aortic incompetence but with or without aneurysmal dilatation (which may be on the point of rupture), and in the majority of cases of congenital heart disease (possibly with bacterial endocarditis). It would not be justifiable to consider all such cases fit for operation because the cardiac index was normal. On the other hand, a common cause of a high cardiac index is the rise of systolic pressure which so often occurs during examination, and this is, of course, not a contraindication to operation. On the basis of the cardiac index alone a large proportion of cases of thyrotoxicosis would be regarded as unsuitable for operation. Patients with aortic incompetence, aortic stenosis, patent ductus arteriosus, or peripheral arteriosclerosis should not be regarded as unfit for operation solely on account of the abnormal relationship of systolic and diastolic arterial pressures.

No one could take exception to the suggestion that the blood pressure should be taken as a routine before operation, but this should surely be regarded as one item in the routine pre-operative examination of *all* systems and not as replacing the "clinical examination of the heart and pulse."—I am, etc.,

A. MORGAN JONES.

Cardiographic Department, Manchester Royal Infirmary.

#### Digitalis a Cardiac Tonic?

SIR,—I have read with interest Mr. Harold Dodd's article on blood pressure and the cardiac index. I must protest at his inclusion of digitalis as a "cardiac tonic." It is well known that digitalis is a cardiac poison, and it is to the effect on the conductivity of the neuromuscular tissues that its therapeutic action in auricular fibrillation is due. Linnell and Thomson (Nov. 6, p. 573) have indicated its uselessness in many other forms of cardiovascular defect.—I am, etc.,

Seascale.

L. GOLDMAN.

#### Treatment of Facial Palsy

SIR,—In his letter to the *Journal* of Dec. 25 Dr. Wilfred Harris has taken the statement, "The test for faradic excitability does not provide any useful information in forming a prognosis," apart from the context and has expressed his disagreement. The statement is not given as the opinion of the annotator but is the conclusion reached by Dr. Karsten Kettel from his investigation of the late results in 264 cases of facial palsy, and it is therefore fair to give his reason for reaching this conclusion. He says:

"In half my cases the paralysis was partial and the faradic test presumably positive, even if in a greatly lowered degree. Since the final result in half the cases of partial paralysis—that is, one-fourth of the total number in this group—was nevertheless bad, it is obvious that the faradic test cannot be a reliable indicator. It is possible that a completely negative test may provide a hint. The fact that the faradic excitability is only reduced does not permit any prognostic conclusion."

On the other hand, the long experience of so distinguished a neurologist as Dr. Wilfred Harris is conclusive. It seems, however, that Dr. Harris refers to cases of Bell's palsy without middle-ear disease, whereas the cases followed up by Dr. Kettel were all secondary either to middle-ear disease or to operative treatment for its relief, and consequently were cases with a greater or less degree of pathological change in the temporal bone as well as in the nerve itself. This may perhaps explain the discrepancy between the observations of Dr. Harris and of Dr. Kettel, and it would no doubt be of interest to your readers to know if this explanation commends itself to Dr. Harris.—I am, etc.,

YOUR ANNOTATOR.

#### Blast Perforation of Ear-drums

SIR,—In the *Journal* of Aug. 21, 1943 (p. 233), Capt. G. W. Palmer reports his findings in 60 cases showing blast perforation of the ear-drum, and concludes that the proportion of infection to be expected is 35 to 40%, "under the most ideal conditions." Some months ago I had the opportunity of examining a similar, though smaller, group of cases, when ten men were admitted to a military hospital following an

explosion in a confined space. Their ears were examined on the day after the occurrence; in all, there were 15 perforated drums, only one having no perforation. In 50 the perforation was in the antero-inferior quadrant, one case showing an anterior and a posterior perforation on both sides. In nine ears there was wax and or blood-clot, and this was carefully removed with Johnson's wax scoop. No ear was syringed, either at the time or later, and no local treatment of any sort employed, except that a piece of sterile cotton-wool was placed in the cone. All cases received chemotherapy for their associated injuries.

No case became infected up to ten days after injury, when the majority of the patients were evacuated. One ear showed a slight blood-stained discharge coming from a piece of blood-clot in the tympanum, which was difficult to remove, but cleared up in four days. One man with a large dry perforation infected the ear through taking a shower bath two weeks after his injury; the infection was a severe one, and a cortical mastoidectomy was eventually necessary. It has been my experience that a higher proportion of surgical mastoiditis is found in infected "blast" ears than in cases of ordinary otitis media.

In my opinion, if local treatment is restricted to the early removal of wax, blood, and debris, a lower infection rate than that given by Capt. Palmer can be expected.—I am, etc.,

B. S. CARTER,  
T. Major, R.A.M.C.

### Tonsillectomy in Children

SIR.—Though wholeheartedly in favour of leaving tonsils in unless there are very definite local indications for their removal, I am sorry to see that your annotation of Sept. 11 (p. 334) accepts statements such as the following: "The sickness experience of the tonsillectomized group was no better than that of children in whom there had been no operation." I beg to point out that there are some serious fallacies in such a conclusion.

1. Tonsillectomy is very frequently incomplete. Some of the largest and most septic tonsils are to be found in children who have had their tonsils "removed." Many studies, therefore, merely compare the health of children whose tonsils were never removed with that of children who, in spite of operation, still have septic tonsils.

2. It is obvious that in the tonsillectomized group there must have been some sort of reason for the operation, such as recurrent colds or coughs. It is a fair assumption that in a high proportion of the non-tonsillectomized group there was no such condition. It is therefore meaningless to compare the health of one group after the operation with that of another, more healthy, group which had no operation.

3. Sinus infection is very frequently the cause of the symptoms for which the tonsillectomy is (wrongly) advised. The symptoms and effects of sinus infection are not relieved by tonsillectomy. Studies of the effect of tonsillectomy without the elimination of a possible sinus infection are valueless.

4. Important causes of the apparent failure of the operation are: (a) persistence of haemolytic streptococcal infection in the throat, shown by Kaiser and others to be common; and (b) a common complication of tonsillectomy—infection of the nasal sinuses. Studies of the subsequent health of tonsillectomized children, with very few exceptions, do not take these factors into account.

The many large-scale studies which I have read are as fallacious to my mind as would be the comparison of the health of a group of patients who had had no stomach operation with that of a group which had had an unspecified operation on the stomach for unspecified symptoms and disease, with unspecified complications and associated infections, and without mention of the completeness or otherwise of the removal of gastric or malignant tissue. What is required is a large-scale study of the health of children who, having no pre-existing or complicating sinus infection, have had, for specified conditions such as nephritis or recurrent colds, a tonsillectomy completely and correctly performed, with elimination of the pre-existing infection, as compared with the health of a similar group of children who, with the same condition, chose to keep the tonsils in and rely on medical and general treatment only. I look forward to seeing such a study.

In addition, it would be interesting to compare the disease experience of children who have had an unsuccessful tonsillectomy, which has failed for the reasons mentioned, with that of children in which the operation was "successful." A mere investigation of the frequency of disease before and after tonsillectomy is fallacious for another reason—the fact that the child is older after tonsillectomy than before it, with all that implies in altered environmental and other conditions.

I regret that the value of a recent paper of mine (*Lancet*, 1939, 2, 1013) on the role of tonsillectomy in nephritis was negated by these very fallacies.—I am, etc.,

R. S. ILLINGWORTH.

### Mastoiditis in Infants

SIR.—I note in Dr. P. W. Leathart's article on a common cause of diarrhoea, vomiting, and dehydration in infants (Aug. 7, 1943, p. 168) the following statement: "We may conclude, therefore, that mastoiditis is commonly caused by milk, vomit, or infected mucus entering the Eustachian tube in children who are either too young or too ill to sit up, and are accordingly nursed and perhaps fed while lying on their backs." In five years' busy practice in this area, containing 50,000 people who treat their young and sick children as described, I have not seen one case of acute mastoiditis. Possibly one case a year occurs for the whole city and surrounding district. I conclude, therefore, that some additional factor is required in young and sick children.—I am, etc.,

Rockhampton, Queensland, Australia

R. PALMERSTON RUNDLE.

### The Psychological Approach to Illness

SIR.—It is regrettable that there is such a gulf between the skilled psychotherapist and his medical colleagues, and that the general principles of the psychological approach to illness are not more widely taught. The proportion of medical psychologists to the rest of the profession is very small indeed—far too small to deal with the cases that should be referred to them. But before patients can be sent to the psychologist they must be recognized as suitable cases, so that some knowledge of psychology is essential to surgeon, physician, and general practitioner alike. How many deflected septa and appendices would be left alone; how many "cardiacs" would live a full life; how many gastritis, headache, lumbago, and colitis cases would be recognized for what they really are, if this outlook were more general? Many cases of neurosis can be greatly helped without any elaborate knowledge of psychotherapy, and many patients can be prevented from developing neurosis by early explanation and guidance. Here is the G.P.'s opportunity and duty.

A simple example of this, but in my opinion a very important one, is in ensuring the right attitude of the "toddler" to his new baby brother or sister. Many parents are so stupid that without definite guidance they switch all their affection and interest to the new arrival, leaving the elder child, previously the centre of interest, lonely and forsaken. It is hard to estimate just how much harm this may do, but it is certain that the personality may be permanently affected and an anti-social reaction developed. The elder child, craving attention, may feign illness, develop enuresis, or even attempt secretly to injure the "usurper." Later on antagonism between the members of a family may persist long after the reason for it has ceased to exist. It is remarkable to know that all this may be prevented by instructing the parents how to behave to the elder child by making him a "partner" in the new baby, encouraging him to help with baby's toilet, and above all by giving him extra affection and attention. All this may seem ridiculously obvious, but how often do we do it?

From Servicemen who come to see me when on sick leave it is obvious that many cases of neurosis are unrecognized and labelled as some "itis" or other. I have recently seen two pilots who were both, as a result of their experiences, just plain scared of flying. After careful questioning they both admitted that that was their whole trouble. But had they been referred to a psychologist? No; both had been in and out of hospital for months, one labelled "chronic catarrh and sinusitis" and the other "bronchial catarrh." A sailor who was suffering from home-sickness was kept in bed for weeks with a diagnosis of "myocardial weakness." I knew the man and referred him to a cardiologist, who reported that his heart

was perfectly normal. Needless to say, such treatment does not cure the neurosis, but leads the sufferer on the way to permanent invalidism.

Have we not all at some time been guilty of accentuating and fixing a neurosis by taking the symptoms at their face value and treating them as organic? One of the worst examples of this I have seen, because it should have been so obvious, was a case of aphonia. The patient, a young woman, had suddenly found that she could speak only in a whisper. The trouble was diagnosed as laryngitis, and her tonsils were removed. She still whispered, so all her teeth followed! I saw her when she had whispered for two years, and under light hypnosis she recovered her normal voice in twenty minutes.

Failure to recognize the psychological nature of certain complaints may lead to elaborate research reaching erroneous conclusions. I have in mind various work done on the problem of enuresis. Enuresis is usually psychological in origin. I saw a girl of 20 some months ago who was living at home and wetting the bed every night. I advised her to join the Services, which she did reluctantly, fearing to disgrace herself. I saw her recently. She is well and happy and the enuresis ceased from the time she left home. Yet we still read articles describing experiments with this and that drug, comparing results with different techniques. But when good results are obtained they are due to the suggestion of cure given by the doctor. Hence the wide divergences of results as shown by the statistics of different workers.

What I plead for, as a humble general practitioner, is a wider teaching of the psychological outlook, so that we may not encourage neurosis but help to eliminate it. A few lectures given as part of the degree course by a psychiatrist whose job is to deal with the pathological mental case are not enough. What is needed is teaching by a psychotherapist burning with zeal for his subject. How well I remember, twenty years ago, attending a course of lectures at Birmingham University given by real enthusiasts, including Hadfield, Bernard Hart, and Crichton-Miller. The whole subject is so absorbingly interesting that if presented properly the student could not fail to learn. Could not one of the outstanding men with a gift for lecturing tour the universities and so revolutionize the outlook of the student? This is not just another subject to be crammed into the medical curriculum, but a question of giving the next generation of doctors a more balanced outlook on medicine and a wider understanding of their patients as individuals rather than as cases.—I am, etc.,

Halesowen, Worcs.

HERBERT W. BLAND.

### Shock Treatment of Mental Disorder

SIR.—In the *Journal* for Dec. 25 (p. 829) Dr. Winnicott invites discussion upon the shock treatment of mental disorder. He writes a curious letter. Indeed, if it were not for the fact that he is himself a leading exponent of Freudian doctrine, one would be tempted to suggest that the treatment in question had aroused his own unconscious hostility. If anyone was so ill advised as to voice his objections in such emotional terms to recent psycho-analytical theories, he would no doubt be referred sternly to the ascertained facts, and told that his own unconscious mind was distorting his powers of observation.

In Dr. Winnicott's eyes we must be very guilty indeed. At this hospital we have been using electrical shock therapy for 2½ years. During this period we have treated a large number of patients, mostly suffering from comparatively mild and recoverable illnesses. Our experience has taught us that the treatment is of unequalled value for cases of depression of psychotic type. Dr. Winnicott speaks of the value of recent researches in psychology, yet we ourselves have no knowledge of any other form of treatment which would cut short this disorder. Despite its recoverable nature, the duration of the attack may be exceedingly long, and our ability to terminate it quickly by shock therapy has taken a load off our shoulders, which does much to overcome our natural dislike of the method.

We have not abandoned psychotherapy; indeed, the rapid removal of the state of acute depression, during which analytical psychotherapy is largely contraindicated, has given us more time for treatment when the basic mood disturbance has been overcome.

We have used the treatment cautiously and in an experimental frame of mind in certain other types of illness. We are not at all impressed with its efficiency in exogenous anxiety states, or, indeed, in any condition in which the mood disturbance is not a fundamental feature of the illness. Far from enabling us to do our work "without having to know anything about human nature," we have found that differential diagnosis assumes a new importance. The problem of distinguishing between an essential mood disorder (an affective psychosis) and a mood disorder which is secondary to the patient's immediate preoccupations (an affective neurosis) can be very difficult indeed. For many it was once a distinction without a difference; now a correct diagnosis may lead to the rapid relief of symptoms by shock therapy in the psychosis, whereas in the neurosis this treatment is likely to make confusion worse confounded. It should be added that there are many cases in which a psychotic depression is grafted on to an underlying neurosis. In such cases the need for psychotherapy after the conclusion of shock therapy is obvious, but we believe that it is no less important in the more straightforward depressions.

We hope very shortly to have the privilege of publishing a series of cases of "mild" and recoverable disorders which have been treated at the hospital. We believe that our results have been excellent and our complications few. We welcome the introduction of a method of physical therapy which is so dramatically restorative. We believe that it represents one of the greatest milestones in the history of psychiatric treatment, and we hope that it will lead to a new understanding of the physiological processes underlying mental disorder. In fact altogether we think that Dr. Winnicott is giving a brave but rather futile imitation of King Canute.

Lastly, about the children whom Dr. Winnicott desires so earnestly to protect from this awful treatment: a moment's reflection should serve to reassure him, for as a good psychiatrist and paediatrician he will surely be aware that psychotic states of depression are exceedingly rare before puberty. As an additional point of reassurance it is noteworthy that electrical shock therapy causes the patient very little discomfort or anxiety.—We are, etc.,

C. H. ROGERSON,  
B. ANDRATSCHKE.

The Cresset Hospital for Functional  
Nervous Disorders.

SIR.—The advocates of shock therapy are likely to react to Dr. Winnicott's seathing indictment with angry protests. But Dr. Winnicott is fundamentally right. One may go further and ask whether some of our psychiatrists are not barking up the wrong tree. Spontaneous recoveries from mental illness are not unknown, and for this reason many methods of treatment which have not produced a higher percentage of cures than no treatment at all might very well be discarded without more ado. Their success cannot be ascribed to any inherent virtue of the method. Yet some mental hospitals still advocate these methods merely because they happen to be fashionable.

Any treatment which does not "cure" as many patients as no treatment at all in the same period of time is doing definite harm. It is drawing wool over the eyes of a long-suffering public. Treatment of mental disorder by the induction of fits is indeed "a wonderful way of doing psychiatry without having to know anything about human nature." If it really is "a by-pass to true understanding of human nature," then its indiscriminate use is to be deplored. It is a fact, as Prof. Ryle states (Nov. 20), that the sciences and techniques have come to dominate medicine to the exclusion of the most important science of all—the technique of understanding. "Science without humanism may work with atoms, but it will not work with men."

The danger in the present widespread use of artificially induced fits as treatment of mental illness is that a potent therapeutic agent is put into the hands of practitioners who often have little understanding of psychotherapy and still less knowledge of human nature. As a safeguard I would suggest that the use of shock therapy should be restricted to patients who are inaccessible to other forms of treatment, that it should be followed in all cases by psychotherapy, and, most important of all, that shock treatment should be given only by practitioners who have had extensive experience of psychotherapy.—I am, etc.,

Wimborne.

J. STEPHEN HORSLEY.

## Population Problems of India

SIR.—Prof. Blacklock (Dec. 25, p. 805) gives a dismal future for India. He concludes that, given all the advantages that modern knowledge can give "to the betterment of the health of man by attention to the prevention of disease and to improving housing, environment, and nutrition, then India... will be so rapidly populated that starvation will inevitably result, and that soon." Before accepting this Malthusian prognostication and its implications there are certain facts about the productivity and population of India which should be considered.

Owing to the methods of agriculture the soil of India, which is not a poor one, is yielding less and less. Manure is used as fuel and straw as cattle fodder instead of manuring the land. Owing to primitive methods and the small average area per cultivator the yield per acre is low and the labour wastage is very high. "More than one-third of the existing cultivable area in India has not yet been brought into cultivation, and the existing cultivated area is cultivated under such restricted primitive conditions as to result in a yield per acre about one-third of that obtained for a similar crop (comparing wheat yields), with less man-power, in the United Kingdom" (P. Dutt in *India To-day*).

## Agricultural Area of British India, 1935-6

	Millions of Acres
Net area by professional survey .. .. .	667.4
Area under forest .. .. .	89.5
Not available for cultivation .. .. .	145.0
Cultivable waste other than fallow .. .. .	153.6
Fallow land .. .. .	51.0
Net area sown with crops .. .. .	227.9

(Statistical abstract for British India, 1946)

Even under these conditions India is producing enough food to give 88% of its existing population a daily ration of 2,800 calories per head if none was exported and there was no maldistribution (Prof. Mukerjee, *Food Planning for Four Hundred Millions*, 1938). But if all the advantages of civilization envisaged by Prof. Blacklock were applied to India's agriculture we see that the country could produce nearly four and a half times as much food, which should be sufficient for a population three times that of present-day India.

As human knowledge advances the productivity of the world will increase; the recent reports published in the *Journal* on the production of protein by the use of yeast are an indication of what we can look forward to. The increase of population in India may well result in a more thickly populated India, but there are many other countries which are more densely populated, including England and Wales. The birth rate in India is apparently declining; in the decade 1901-10 it was 38, in the decade 1921-30 it was 35, and the average rate for the 5-year period 1934-8 was 34.5.—I am, etc.,

M. BARROW.

Birmingham.

SIR.—In his gloomy forebodings Prof. D. B. Blacklock (Dec. 25, p. 805) having enlisted the services of pessimist Malthus, I feel constrained to reply by invoking the aid of optimist Doubleday.

Doubleday was a very worthy citizen of the city from which I write, and in *The Natural History of Population* Raymond Pearl (surely an acceptable sponsor on such a matter) says of him: "Doubleday's book, now largely forgotten and almost never read, contains with all its errors of judgment some acute observations and reasoning." The pith of Doubleday's theory, which appeared in his *The Law of Population* in 1842, is, in his own words, that "overfeeding checks increase, whilst on the other hand a limited or deficient nutriment stimulates and adds to it." In essence he seeks to establish the existence of a natural self-adjusting and variable fertility potential in the human race, and though clearly nobody would set out to claim that this theory is the whole truth, it is, at the same time, not one wholly to be dismissed. Raymond Pearl, for example, draws attention to researches of Sydenstricker's on the high expressed fertility of those on the dote, which lend colour to Doubleday's observations.

Some association between the standard of living and potential fertility such as Doubleday describes would, in due course, mitigate the miseries which Prof. Blacklock fears may arise out of the Atlantic Charter, and would render it an experiment worth pursuing.—I am, etc.,

IAN E. MCCracken.

Newcastle-upon-Tyne.

SIR.—You are to be congratulated on the publication of an extremely valuable and important article on the population problem in India. It is good to know that the pages of the *British Medical Journal* are available for such sound thinking. One point only calls for comment. Toward the conclusion the author says: "To what extent, if any, the frequent use of chemical or mechanical contraceptives finally impairs health is as yet by no means certain." Records at our clinic have not been accumulating for twenty-two years, and it is quite certain that though some mechanical and chemical contraceptives do have a detrimental effect on health, yet the perfectly safe occlusive method combined with a bland suppository for women need cause no anxiety, for they cause no harm.—I am, etc.,

MARIE C. STOPES,  
Founder of the Mothers' Clinics.

## Artificial Insemination

SIR.—Many will endorse Dr. Todhunter's courteous and timely warning (Jan. 1, p. 25) about the discussion of the pros and cons of artificial insemination. He stresses the importance of wise and true teaching and advice so far as our present knowledge takes us.

I suggest that our sins of omission are as great and far-reaching as any active false teaching, and that a brake should be applied to the development by Press comment, advertisement, radio, etc., of the increasingly prevalent idea that the medical profession has become so clever that a physical Utopia is just round the corner. We shall be blamed and seriously discounted in our efforts when the public become disillusioned, unless, meanwhile, we actively avoid any such claim to infallibility and combat false ideas already taking root.

So much excellent research has been done and is in progress that the average doctor is so busy keeping in touch with the newest therapeutic agent, with so many per cent. of indications and cures, that he tends to forget the fundamentals of anatomy, physiology, pathology, and psychology, all of which change only very little and very slowly. The reproductive function is the most important and the most mysterious in human experience. The essential basis of civilization lies in the control of intrasexual physical relationships. Therefore it becomes of extreme importance, when civilization is so precariously balanced, that the medical profession must not allow false teaching to go unanswering.

In recent years much preventable psychological uncertainty and distress have been caused by such ideas as (a) sterility is curable by hormones, vitamins, etc., if only the correct combination is used; (b) that no woman's life or even health should ever be in jeopardy in pregnancy or childbirth; (c) that the converse of contraception is true—i.e., that a woman can have a baby at will—to take easy examples. Perhaps that last, of all the many false notions prevalent now, causes the greatest social and psychological trauma. Nearly all young people to-day marry honestly believing that contraception for the number of years necessary to establish a material and social position is the wise and enlightened procedure. They are greatly surprised, confused, and hurt when the proposed baby does not materialize. Even at that stage they are allowed to believe that medical science can put matters right. Only sometimes is this true, and even when all means are used it remains for Nature, Providence, God, or what name you choose, to perform the miracle of conception. How much better it would be to acknowledge our fundamental ignorance, and to advise young people to marry honestly and generously to make love, and to welcome gratefully the miraculous result! Then and only then, after the family is established, should any question of contraception be considered.

It behoves us, if we are to maintain our position as an intelligent profession, to retrace our steps a little, to accept all experimental advances only in relation to our essential bases of knowledge, and to avoid the arrogance of partial knowledge so dreadfully suggestive of Continental doctrines and of quackery.—I am, etc.,

Birmingham.

J. S. M. CONNELL.

SIR.—I see no more objection to artificial insemination with the husband's semen than assisting the child into the world

with forceps. But when it comes to using "donated" semen, another question arises: What will be the status of the child? If the husband gives his name as the father he will be liable to prosecution, and if the real father's name be given or the name be omitted the child will be labelled a bastard.—I am, etc.,

Birmingham.

ROBERT ANDERSON.

### Consciousness in Senescence

SIR,—I have read with great interest the paper by Prof. Jefferson on the nature of concussion and your editorial on the place of consciousness (Jan. 1). I note that no reference has been made to the anatomical and physiological changes that occur in the course of senile degeneration, but the close resemblance between the manifestations of this condition and those of concussion and of cerebral lesions generally would appear to make this a very valuable field of comparative inquiry. The fitful gleams of consciousness alternating with an almost stuporous condition which occur in advanced senility, the sudden falling asleep, the disorientation, the defective ideation, and the narrowed field of consciousness are similar in old age and in traumatic cerebral conditions.

Senescence is regarded as due to an arteriopathy, and the variability of the symptoms from day to day and from hour to hour is undoubtedly due to the fact that different elements of the brain receive a different amount of blood supply from time to time. It is obvious that all levels of cerebral function are affected, from those that are associated with the higher centres, which are considered to be situated in the cortex, to the more elemental functions, which are regarded as emanating from the hypothalamic regions and the brain-stem.

From the cases of senescence which I have personally observed, my own impressions are that consciousness, in the widest sense of the term, is an extremely complicated function dependent on the integrity of the brain as a whole.—I am, etc.,

London, W.1.

DORIS ODUM.

### The Nature of Concussion

SIR,—In his article Prof. Jefferson concludes that a paralytic effect upon the neurons is the prime cause, but it is not at all clear how this primary paralytic effect can be produced by the small subcortical focal lesions which he gives as examples causing stupor, nor how it is related to the stupor-recovery-stupor sequence which he knows holds the key to the problem.

Since I have shown that the function of the frog's peripheral nerve is unaltered by stretching or compression within reasonably wide limits, and Echlin has shown that slight stretching is an adequate stimulus to cause cerebral capillary constrictions, it seems more probable that the primary effect of tissue distortion by concussion, blast, or small focal lesions with surrounding oedema, is a capillary stretching and constriction. I have discussed (*B.M.J.*, 1938, 1, 265) how patterns of capillary flow within brain tissue can influence group neuron function, and said that a normal change of pattern is allied to change of mental and emotional phenomena, so that a primary constriction of certain cerebral capillaries due to stretch, and a secondary paralysis of neuron function from capillary anaemia, elucidate the problems of stupor from subcortical lesions, and of the neurological and mental effects of concussion.—I am, etc.,

Birmingham.

F. A. PICKWORTH.

### Teaching of Anaesthetics

SIR,—Dr. K. G. Lloyd-Williams's letter (Dec. 25, p. 827) is both timely and welcome. Although not in agreement with it all, I most whole-heartedly agree with the urgency of a complete revision of both the teaching and the practical administration of anaesthetics. Realizing early in my career how anaesthesia can either make or mar a surgeon's best efforts, I saw that advances in surgery were difficult and hazardous if they were not supported by adequate advances in anaesthesia. After visiting many of the bigger Continental clinics over the years, it became more and more obvious that inhalation methods of anaesthesia were increasingly giving way to basal narcosis combined with peripheral infiltration, and

other better and safer methods for the bigger surgical enterprises.

After giving most methods a prolonged trial—and these included all types of inhalation, spinal, paravertebral block, the barbiturates, etc.—I adopted a combination of tribromethyl alcohol and peripheral infiltration with "planocaine," and have used this for years for operations of all magnitudes, including the severest types of emergency, with results that are incomparable with any other method I have seen. For intra-abdominal work splanchnic or mesenteric block is used in addition. This combination, or improvements on it, have come to stay, and, though nearing the autumn of my years, I forecast appointments of "surgeon-anaesthetists" at our larger clinics. Let, then, the training of the anaesthetist of the future begin in the anatomy and applied physiology departments, where he or she will acquire a more accurate knowledge of the anatomy of the cutaneous sensory and splanchnic nervous systems, and a more thorough appreciation of such a vast subject as the applied physiology of shock.—I am, etc.,

Ballidon, Yorks.

BASIL HUGHES.

### Medical Boarding for the Merchant Navy

SIR,—In recent months various letters under this heading have appeared in the *Journal*. Mr. Greany, the secretary of the Shipping Federation (Oct. 2, p. 435), indicated that the question of medical arrangements in the Merchant Navy was too lengthy and complex to be dealt with in correspondence columns, and at the same time corrected some misstatements of fact which had appeared in some of the letters.

As one who has been connected with the medical aspects of seafaring for nearly thirty years, I would like to emphasize that the Shipping Federation, the shipping companies, the Ministry of War Transport, and the various unions connected with the Merchant Navy are fully alive to the many problems about the fitness of seamen, and that the particular difficulties which have arisen owing to wartime conditions have not escaped their notice. They are all giving much attention to them, and there is active co-operation between these bodies to this end.

Dr. Royds Jones (Dec. 25, p. 831) rightly states that there has been little trouble with the regular pre-war seafaring man. The difficulties are more with those directed back to seafaring by the Ministry of Labour and those who have started seafaring since the outbreak of war. Many of the "old hands" might not have reached Grade I or II standard of the armed Forces medical boards had they been before such boards, but they have been on voyage after voyage, serving magnificently, and doing their jobs efficiently without complaint, frequently in spite of advanced age and some physical defects. Only recently I examined a boatswain who had been at sea for over fifty years, the last forty-three years with one shipping company, and thirty-five years in his last ship, only retiring at the age of 71 after an accident that was no fault of his years and which would have incapacitated a man thirty years younger. Without any hesitation I would rather trust the judgment of the Shipping Federation medical examiners and the medical officers of the various shipping companies as to the fitness or otherwise of seafaring men than the findings of the average armed Forces medical board.

Dr. Royds Jones suggests medical history cards for every man. These were started last September, and there is now a record card for each man as soon as he enters the Reserve Pool, and part of it is devoted to medical history. The findings of all examining doctors are entered on the card, and entries are also made in respect of general practitioners' certificates, hospital reports, etc. By this means a check can now be kept on those who try to "go sick" too frequently or at inconvenient times just before a ship is due to leave United Kingdom waters, and we can now take steps to prevent recurrence of some of the troubles that have existed in the past, though the malingerer or shirker will always be a difficult problem, as for obvious reasons the same action cannot be taken in the Merchant Navy as in the fighting Services, where the men are supervised and controlled whether at work or not.

Medical certificates of unfitness from general practitioners when the man is ashore are often a difficulty and do complicate the work of the Shipping Federation and shipping companies' medical officers. Under the Reserve Pool arrangements,

however, all such seamen must submit, if required, to an examination by a Reserve Pool doctor, who can, if necessary, obtain a second opinion or refer the case to the medical referee appointed by the Ministry of War Transport.

It is impossible to go into all the details of medical arrangements concerning the Merchant Navy in a letter which could be published. There are difficulties to be overcome and there are defects which are not denied, but it is quite wrong, as some of the letters have suggested, to think that those responsible are doing little or nothing about it. The whole question is constantly under review and active steps are being taken to overcome the difficulties and remedy the defects.—I am, etc.,

E. L. CALDWELL-SMITH.

Chief Medical Officer, the Shipping Federation and  
Merchant Navy Reserve Pool.

London, E.C.3.

### Colonial Research

SIR.—The demand for research and ever more research raises the questions, "Have results justified the large sums already expended?" and "Is research organized on the right lines?" Looking back on the chief achievements in research into tropical diseases, one is struck by the fact that it was the ordinary doctor, often working single-handed and engaged in medical work, who made the outstanding contributions. Ranson, busily engaged in practice in China, discovered the role of the mosquito in filariasis; Ross, as a young I.M.S. officer in India, that of the mosquito in malaria; Forde, a medical officer on the West Coast, discovered the trypanosome of "negro lethargy"; Stannus minutely described pellagra, a disease then hardly known to English doctors, among the inmates of a gaol in Nyasaland, and discredited the maize causation theory—a discovery which has led to recognition of the disease in many parts of Africa and the U.S.A. and has stimulated much work on deficiency disease.

All these men were busily engaged in their general professional work. The true research worker is very much of an individual; his gifts seldom fructify in the atmosphere of a large fellowship. Research of this individual character, which, as Ross has recounted, often enough received little encouragement, has, I venture to say, been far more fruitful than that of large commissions, and infinitely less costly.

Nowadays the multiplicity of duties inflicted on the successors of these men almost debars reflection on what they have observed at the bedside or in the post-mortem room. They are overwhelmed by report-making, clerical duties, examinations of labourers, of officials of all races on appointment, on going on leave, on postponing of leave, by medical boards, the examination of school-children of all races, court cases, as well as by the expanding work of hospitals. I speak from recent experience in Tanganyika, where much military work also, at the moment, falls upon them.

I suggest that in the medical field far more will result from increasing the staff of district medical officers and lightening their burden of work than from appointing organized bodies of workers who are not in intimate contact with the sick. Help from specialists is, of course, required from time to time and should be obtainable from a central laboratory, and there will always be questions requiring team work for their solution. But it should be possible to relieve a man who has initiated a promising investigation from much of his general work.

The opportunity for individual research was one of the main attractions of the Colonial Medical Service. This attraction hardly exists to-day.—I am, etc.,

J. B. DAVEY

(Formerly F.M.O., Tanganyika).

Bournemouth.

### Hospital Diets

SIR.—Referring to your previous correspondence on inadequate hospital diets, may I record the case of a Service patient admitted to this hospital recently from an R.A.F. hospital, which I shall leave unnamed, who had been under treatment for pulmonary tuberculosis and diabetes mellitus. He brought with him a diet sheet, a copy of which, for the purpose of refreshing and possibly tantalizing the memories of some of your readers, I append.

To counteract these daily spreads he was given 80 units of insulin. A few days on normal hospital diet—and the diet here is considered to be better than average, even by the

1st Day	2nd Day	3rd Day	4th Day	5th Day
<b>Breakfast</b>				
Bacon and egg, toast and butter	Porridge, bacon, toast and butter	Scrambled egg and bacon, toast and butter	Porridge, fish or salmon (salmon and egg to bind), toast and butter	Liver and bacon or egg and bacon, toast and butter

Lunch break: milk, half a pint, with biscuit

<b>Lunch</b>				
Steak or minced beef, potatoes, cauliflower, stewed apples, cornflour sauce	Mutton mulligatawny, peas, stewed peaches	Chicken, potatoes, green vegetables, apple or prune tart	Beef stew, onions and carrots, tinned peas, potatoes and green vegetables, stewed fruit	Fish, potatoes, green vegetables, rice pudding and milk

<b>Tea</b>				
Sardines, bread and butter, salad, tea	Boiled or poached egg, bread and butter, salad	Salmon, salad, bread and butter	Cheese salad, bread and butter	Cold meat or ham or tongue, bread and butter, salad

<b>Dinner</b>				
Chicken or liver or lean pork, potatoes, peas, green vegetables, stewed apricots or prunes	Steamed or grilled fish, potatoes and green vegetables, Welsh rabbit	Grilled steak, onions, baked potatoes, bread-and-butter pudding	Mutton, potatoes, green vegetables, rice pudding and baked apple	Savoury mince, potatoes, carrots, fruit tart

13 oz. milk and two biscuits and butter every evening.

present patients—and his daily insulin requirements were reduced to 25 units, resulting not only in a saving of insulin but a feeling of repletion after meals, and the comforting knowledge that upon discharge he will be able to obtain, and pay for, the commodities which now figure in his diet.

Perhaps there is something to be said for bad diets.—I am, etc.,

R. LIVINGSTONE,  
Medical Superintendent.

Kettwell Hospital, Swanley, Kent.

### Effect of Pregnancy and Parturition on Pulmonary Tuberculosis

SIR.—In view of the increased incidence of pulmonary tuberculosis in recent years, Dr. R. C. Cohen does well to call attention in the *Journal* of Dec. 18 (p. 775) to the effect of pregnancy and parturition on pulmonary tuberculosis. His results and conclusions in those cases in which the disease is quiescent or arrested are in accordance with the views of most tuberculosis workers, but in those cases in which there is clinical or radiological evidence of active disease his conclusion that "active pulmonary disease is seldom accelerated by pregnancy and labour" is at variance with both generally accepted beliefs and the results of his own investigation. Dr. Cohen finds that out of twenty-five such cases no fewer than seven showed retrogression of the pulmonary disease, and in only two out of these seven cases was subsequent improvement noted. He does not give details of the twenty-five cases, which he has included under the heading "Progressive," and he makes no mention of having carried out any investigation of patients with similar pulmonary disease and who were not pregnant, but states that "there is no reason to assume that the disease in the former would not pursue its steady and relentless course."

It is well known that the Essex County Council Hospital, Black Notley, is an institution for early and treatable cases and not for cases of advanced disease; this being so, it would be very surprising indeed to find anything like such a high figure as 28% of their cases with active disease showing

evidence of retrogression while still undergoing sanatorium treatment. On the evidence which Dr. Cohen puts forward it would therefore seem that pregnancy and labour do in many cases have serious consequences; and his results would seem to show that in any case where a woman with active pulmonary tuberculosis is seen early in pregnancy the question of terminating the pregnancy should be very seriously considered indeed.—I am, etc.,

R. S. McDADIE,  
Deputy Medical Superintendent,  
Essex County Hospital, Chelmsford.

### Scabies

SIR.—The letters from Major Kenneth Mellanby (Dec. 18) and Dr. A. M. H. Gray (Dec. 25) following Dr. Henry MacCormac's article of Nov. 27 interested me. The City of Portsmouth instituted a central clinic for the treatment of scabies in January, 1942, and during that year treated some 5,400 cases and contacts (average, one contact to three definite cases). Great care was taken with the disinfection of bedding and clothing. In the spring of this year, following Major Mellanby's experiments, the M.O.H. decided to omit the disinfection of bedding and personal clothing. The number of cases treated this year seems likely to be some 550 fewer than in 1942.

Much of this reduction may be due to our keenness in roping in and treating contacts, but, on the other hand, omission of disinfection, if Dr. MacCormac is right, should tend to favour an increase. Actually I have had very few complaints that infestation was due to blankets (Home Guard, fire watchers, etc.), and on detailed investigation I have been unable to trace a single authenticated case. In one instance the culprit was indeed infested, but with lice. In another he was shown to be suffering from psoriasis, the diagnosis, of course, being made by the complainant. I am not suggesting that blankets never transmit scabies, but in view of the labour and petrol saved I agree with Major Mellanby that the disinfection by a public body could be omitted. In my opinion it is far more important to see that immediate contacts are treated, even when, as is usually the case, they show no visible signs of scabies. I despair when a contact brings along a certificate from his doctor: "I certify that none of this family shows signs of scabies."

Like Major Mellanby I find many cases showing dermatitis from the use of sulphur—usually forearms and front of thighs—with scabies elsewhere. Out of 3,641 cases (excluding contacts) treated in 1942 83 showed dermatitis due to sulphur or dettol. I take this as an argument against the home treatment of scabies. Very few patients are conscientious enough or can be trusted to treat themselves properly at home.

I may say that we use a 25% solution of benzyl benzoate made up by ourselves, with two coatings given at one attendance. Occasionally I find it necessary to give a second application.—I am, etc.,

ERNEST SHAND,  
Assistant Medical Officer of Health, Portsmouth.

### Medicine in Persia

SIR.—The formation at Teheran in September last of an Anglo-Iranian Medical Society is, as you well say (Dec. 25, p. 820), a "pleasant instance of the close relations between this country and Persia." It is, however, so far as British medicine is concerned, but the most recent instance of many over a century and a half. Doctors are nowhere more esteemed than in the country of Avicenna, and since fully qualified Persians have, so far, been few for its vast size and difficult communications, heavy responsibilities have fallen on their foreign colleagues. The story of the work in treating the sick, in public health, and in training hospital assistants, of medical officers in British and Indian Government employ, of C.M.S. (and American) missionaries, and of doctors of undertakings such as the oil company, cannot be told now. You may, however, allow me to add a postscript to your welcome to the new society. Even it had a modest forerunner that was also of British inception. This was the Teheran Medical Society. As in September, 1943, so in March, 1924, Persians, British, and Americans were at the inaugural meeting, and also a French surgeon, a German, and, strange

to say, a Japanese—the medical member of a visiting mission. Further, you name a link between the two events, for Dr. Habibi Adlé, president of the Iran Medical Society, was one of our original members. My theme leads me to add that, about the time in question, he gave up practice in Paris when, on the advice of two British medical officers who had been appointed to reorganize it, the Persian authorities nominated him the first radiologist to their hospital at Teheran. It is pleasant but no surprise to learn that his abilities have brought him high office, and that he is using it to support the new society.—I am, etc.,

A. R. NELIGAN  
(One-time Physician to the British Legation  
at Teheran).

Droitwich.

### Sulphathiazole Insufflations for Gonococcal Vaginitis

SIR.—I note with interest and appreciation Prof. O'Donel Browne's remarks on this method of treating gonococcal vaginitis and endocervicitis (Dec. 25, p. 816). This form of treatment is not new. Personally, I have used this method for a considerable time and must admit that my results in many cases are not "dramatic." Recurrences and drug-resistant cases are too common. I favour at present a short few-days treatment (oral as well as local), giving 5 g. sulphathiazole daily (divided 4-hourly) by the mouth with plenty of water, and vaginal insufflation once daily with approximately 2 to 3 g. around the external os and in the fornices. Close supervision is necessary.

Trichomonad infection coexistent with gonococcal infection is commonly found at the V.D. clinic. In such cases vaginal insufflations with "picragol" or with "acetarsol vaginal compound" powder or the nightly insertion of "S.V.C." tablet (stovarsol vaginal compound) are necessary long after sulphathiazole treatment has been stopped.

Many venerologists will have welcomed Prof. Browne's remarks on this form of treating gonococcal infections. The experiences and opinions of others would, I am sure, also be of value.—I am, etc.,

C. HAMILTON WILKIE,  
Director of V.D. Services, Leicester.

### The Septic Finger

SIR.—We have been following with extreme interest the correspondence on septic fingers. While we should like to reiterate Dr. Romer's well-conceived opinions, we find ourselves in disagreement with those of Dr. Bailey. We should like, therefore, to make the following comments:

1. Most of the fingers that we see are definitely "over-ripe" and less than 5% are at the stage of invasion.

2. We are extremely surprised that Dr. Bailey has not seen any cases with bone necrosis, and we should be very interested to hear if any radiographic investigations were made of suspected cases, as we have seen several in the last few months.

3. Although it is obviously desirable to reduce the number of out-patients, it is our experience that the majority of general practitioners have neither the time nor the facilities to treat these septic fingers after incision.

4. We would further point out that septic fingers rank high as a cause of loss of man-hours in war production and of permanent disability; thus the greatest possible care should be taken in their treatment.

5. We have found short-wave diathermy an excellent means of rapidly healing those cases of prolonged infection with or without early bone involvement.

It is possible that, being house officers in a hospital seeing only some 200 casualties a week, we have better opportunities than Dr. Bailey for continuing treatment of our septic fingers until they are completely healed.—We are, etc.,

M. V. P. THOMAS,  
LEONARD L. MISTLIN,  
CYRIL BORODA.

Watford.

### Physics and the Surgeon

SIR.—I read with great interest the Bradshaw Lecture by Mr. H. S. Souttar (Dec. 11, p. 737) on physics and the surgeon. He states: "The radiation of which I am speaking consists of ether waves transmitting energy across space." I think it only fair to point out that there may perhaps not be an ether of space but just space (or space-time of relativity). With the

advent of Einstein's relativity, it has often been said that ether has been abolished. Either merely is a convenient noun to describe the properties of space. It is often a convenient grammatical construction to have. If we persist in using the term ether, it should be understood as the subject of the verb "to undulate," and acts as this subject t. t. well. The term ether as understood by the old physicists is no longer believed by modern scientists.—I am, etc.

Public Health Department, Governor

G. E. DOUGLAS.

### Agents Provocateurs

SIR.—As there has been a good deal of controversy in connection with this case, it would be interesting to know what obligations (if any) the two doctors who saw the "patients" in the second instance were under as regards the doctor who first dealt with them. Both of these practitioners knew that the decoys had been certified by another doctor, with whose opinion they disagreed; they also knew, presumably, that their findings were likely to be the basis of an action for lax certification against the first doctor. The question which arises is, Were they under any obligation to communicate with him before proceedings were taken?

Considerable public interest has been taken in this case, the general opinion being that the accused doctor had a decidedly "raw deal" all round—I am, etc.

Lester.

E. J. O'SULLIVAN

## Obituary

### C. E. DOUGLAS, LL.D., M.D., F.R.C.S.Ed.

The death at St. Andrews of Charles Edward Douglas not only deprives the Scottish profession of one of its most respected and popular senior members but also robs both the medical charities of a highly valued supporter. After qualifying M.B. at Edinburgh University in 1877 he went on to the M.D. in 1881, the F.R.C.S.Ed. in 1898, and the D.P.H. in 1894. He

had been resident surgeon at the Royal Infirmary, Edinburgh, and assistant physician at Morningside Mental Hospital. An enthusiastic Volunteer, he served in the South African War and in the war of 1914-18, reached the rank of lieutenant-colonel in the R.A.M.C.(T.), and held the Volunteer and Territorial Decorations. He practised at Cupar in Fife for many years and was M.O.H. for the burgh. When the British Medical Association held its Annual Meeting in Melbourne in 1935, Douglas was soon the admired

doyen of the company; it was supposed that he reached the age of 80 during the outward journey, but this was clearly a mistake, as he had just not reached 88 at his death on Dec. 28, 1943. He was especially devoted to chess; and when he travelled home from Marseilles by air it was said that he spent the whole flight in the exercise of this pastime. His spare, almost shrivelled, form threw into relief the constant activity of his mind and body; and his instant popularity with both sexes and all ages was a wonderful tribute to his heart as well as to his head. Douglas was a vice-president of the Royal Medical Benevolent Fund. He was even more of a mainstay to Epsom College, of which he was also a vice-president, and an honorary local secretary over a period of very many years; his own subscription was kept alive for 50 years or more, and his collections from colleagues were further valuable evidence of his interest in education.

C. E. Douglas had long been a loyal B.M.A. man and did valuable work in his own neighbourhood, at the Scottish Office, and at headquarters in London. He was a member of the Central Council for 12 years, and of the Scottish Committee from 1923 to 1930 (chairman 1923-5); he represented his

Division at 13 Annual Meetings of the Association, and served on the Journal Committee, the Insurance Acts Committee, the Ethical Committee, the Charities Committee, and the Parliamentary Elections Committee, taking a particularly keen and active part in the work of the last two committees through a long period of years. He was also a member of the special committee set up by the Council to inquire into the causation of puerperal morbidity and mortality. At the Edinburgh Annual Meeting in 1929 he held office as vice-president of the Section of Obstetrics and Gynaecology. He had been president of the Life Branch in 1914, and in recognition of his long and distinguished service he was elected a vice-president of the B.M.A. in 1936.

On his retirement in 1927, when he celebrated the jubilee of his entry into general practice, Dr. Douglas received the honorary degree of LL.D. from Edinburgh University. He then made his home at St. Andrews, where he took a deep interest in the history of the town and in the administration of St. Andrews Episcopal Church; he was also a member of the Representative Council of the Scottish Episcopal Church. When he left Cupar a public ceremony was held in his honour, at which the Lord-Lieutenant of the County, Sir Ralph Anstruther, Bt., handed him a number of gifts from his many friends in Fife.

### Dr. S. WATSON-SMITH writes:

As the years roll by we have to part with one notable member of the profession after another. Now we lament the passing of Douglas of St. Andrews. He was born at Cannanore in South India, the son of Col. Walter Douglas of the Madras Staff Corps, being, when he reached school age, sent home to be educated at the Edinburgh Collegiate School, then at the University of Edinburgh. While at school he won many long-distance races. On qualifying, Douglas became resident house-physician to Joseph Bell at the Edinburgh Royal Infirmary, and worked for a short time there as surgical assistant to Joseph Lister. Thereafter he spent six months at Vienna in postgraduate study. He began general medical practice as an assistant at Richmond, settling down in 1880 in practice on his own account at Cupar, Fife, having acquired the practice of the late Dr. James Mackie, whose youngest daughter he afterwards married. Soldiering was one of his greatest interests: for 40 years he served in the Volunteer Force, afterwards transferring to the R.A.M.C.(T.) when the Territorial Army came into being. For many years Douglas served as battalion medical officer of the 6th (Fife) (The Black Watch) Royal Highlanders, spending his well-earned yearly holiday in training at camp. On the outbreak of the South African War he at once volunteered for service, being appointed M.O. of the 1st Bn. Worcestershire Regiment. During the war of 1914-18 Douglas served in France at H.Q., 51st (Highland) Division, afterwards commanding the casualty clearing station of the Division. Douglas was founder of the Fife Medical Society, being hon. secretary for the long period of 45 years; was a member of the Medico-Chirurgical Club, of the Harveian Society of Edinburgh, and of the E.R.I. Residents Club, being president of each of these at one time or other. At professional meetings he was often called upon to speak: addressing any meeting he was fluent yet concise and graceful, never diffuse, and always relevant; all his utterances were charged with common sense. He was an easy writer, contributing from time to time to the *B.M.J.* To the Harveian Society of Edinburgh he contributed "Two Medical Humourists"; to the Obstetrical Society there, "Observations on 70 Years of Country Midwifery Practice"; and he was an Alexander Black lecturer, choosing as his subject "The Family Doctor as Specialist."

To measure the good that Douglas did in his day is beyond doing—its extent is immeasurable. Each day of his working life was a full day, and his life a very full one. Practically the whole of his professional life was spent in Fife, which has cradled and given to medicine so many able men. Striving stoutly in his profession, he yet found energy and time for much else: he had an unusual power of work and of steady application. Belonging to a past generation, much of his work has faded from memory, but the good that he has done lives after him. What will live longest in the thoughts of his friends will be his amazing versatility and his high-souled character, for he had many lovable qualities. His wife died in 1939, after 57 years of married life; they were a most devoted couple, extremely happy in their home life. Of his two daughters one, Dr. Dorothy Douglas, is in medical practice in St. Andrews; the other is sub-prioress of the Convent at Bruges, so is for the time being completely cut off from home.

### Mr. H. S. SOUTTAR writes:

To live to a great age is a doubtful boon; to enjoy to the end of a long life all that life has to offer is a rare achievement. In spite of his years Douglas never grew old, and to the very end he

retained an ardour and alertness that we all envied. A voyage round the world in a large party is an experiment that few men of 80 would care to undertake, but when the B.M.A. met in Melbourne in 1935 Douglas was there. No one enjoyed the journey more than he, and there was no more popular member of the party. He was a fine chess player with a consummate knowledge of the game which was always at the disposal of us all. At the end of our tour he wished to return overland from Marseilles, and I persuaded him to come with me by air. He only consented on the condition that we should play chess! I shall never forget his boyish delight in every detail of our journey, and perhaps I owed to that that we agreed to draw our game as we came down at Croydon.

Douglas took a deep interest in the Association and in all the problems of our profession, and I have recent letters from him showing that his interest was unabated to the end. We have lost a wise counsellor and a good friend, but he has left behind memories of deep affection and of high regard.

#### ROBERT OWEN MORRIS, O.B.E., M.D., D.P.H.

By the death of Dr. Robert Owen Morris in his 84th year Wales has lost one of her most notable public men. A correspondent sends the following memoir to supplement the notice printed on Dec. 25:

Morris's career began as a shop assistant at Portmadoc, Caernarvonshire, but deciding to enter the ministry under the auspices of the Welsh Calvinistic Methodists, he returned to school, and then passed through Bala College to Edinburgh. After ordination he ministered in North Wales and was a welcome visitor to the pulpits of both Welsh and English Presbyterian Churches, including those in the Liverpool district. He was a powerful and popular preacher in great demand at special services. On the eve of accepting a call to one of the most prominent churches in North Wales, he decided to leave the ministry and return to Edinburgh as a medical student. He continued preaching in the churches of the Scottish Presbyterians, and was offered ministries in Scotland and America. These he did not accept, but went on with his medical studies and qualified M.B., C.M. in 1894 and took the M.D. in 1898.

He began medical practice at Birkenhead in 1895. A year later he was elected to the school board and was actively associated with education in the borough, first as a member of the board and later as a part-time school medical officer. Though not politically minded, he was prevailed upon to seek election to the borough council as a Liberal, and was successful. The Conservatives were in power during his membership, and Morris, always a powerful and tenacious fighter, was continually in opposition to the leading party. To his amazement, therefore, he was approached by members of the Conservative party in 1902 to accept nomination as mayor of the borough. This he accepted, and served in that capacity in the year 1902-3. At the time he was also serving the council as a part-time school medical officer. The passing of the Education Bill in 1902 debarred municipal employees from becoming members of councils by which they were employed. So that Morris might complete his year as mayor, a special clause was inserted in the Bill enabling officers to continue serving on their councils until October, 1903. Nine days before his term of office expired Morris resigned. After this he interested himself in public health, and when over the age of 50 took the D.P.H. of Liverpool University.

In 1911-12, with the passing of the National Health Insurance Act and the establishment of the Welsh National Memorial Association for the Treatment of the Tuberculous, he was persuaded by Mr. David Davies of Llandinam (now Lord Davies) to undertake the campaign in Wales against tuberculosis. For this purpose he toured the whole of Wales, lecturing in city, town, village, and hamlet. His early training as a minister served him in good stead. Wherever he went he drew crowds. He was able to talk to the public in simple but forceful manner, and his illustrations were always to the point. In Morris's later years the writer sometimes accompanied him to meetings on health matters, and was astonished at the hold he always had on his audience, especially an audience of school-children. The campaign ended, he became director of education for the Association and tuberculosis officer for Montgomeryshire, and in 1926 he took over Merionethshire as well. In these two counties he worked until 1931, when he retired as tuberculosis officer but retained his post as director of education. During his work as tuberculosis officer he travelled always by train, and it is said that no train would leave without him if it were known that he was due to catch it.

On his retirement he lived at Aberdovey, later moving to Fairbourne and then to Llwyngwril, where he died. He continued his lecturing and travelled throughout Wales as in his early days, taking part in health weeks, etc. He was the author of many pamphlets on tuberculosis and a part-author of the Red Cross textbook on tuberculosis. His work as a lecturer and writer gained him his election as Fellow of the Royal Society of Edinburgh. He was awarded the O.B.E. in 1935, and his public services were also recognized by his elevation to the magisterial bench in the borough of Birkenhead and the counties of Montgomery and Merioneth. He was also appointed High Sheriff for Merionethshire. He served as

a member of the Court of Governors of the University of Wales Aberystwyth. As a propagandist in health matters Morris was among those few medical men who could speak to the lay public in simple non-technical language. He was equally at home in English or Welsh.

He was a most lovable personality, jolly and entertaining company, kind and considerate, and a fearless and tenacious fighter when the cause was just. His passing is mourned by many throughout the breadth of Wales.

T. W. D.

## The Services

Temp. Surg. Lieut. J. Saint-Martin, R.C.N.V.R., has been mentioned in dispatches.

Surg. Lieut.-Cmdr. J. D. Lendrum, R.N.V.R., appears in a list of names published by the *London Gazette* as mentioned in dispatches for gallantry or good services in the last six months or more of war.

Wing Cmdr. J. P. Huins, O.B.E., A.A.F., and Acting Wing Cmdr. H. P. R. Smith, R.A.F.O., have been awarded the Air Force Cross.

Acting Wing Cmdr. C. C. Barker, R.A.F., has been commended for valuable services in the air.

The following appointments in recognition of gallant and distinguished services in the Middle East have been announced in the *London Gazette*:

*C.B.E. (Military Division).*—Col. J. R. Boyd, M.C., N.Z.M.F.; Brig. (local) G. W. B. James, M.C., Brig. (temp.) R. F. Walker, O.B.E., M.C., Cols. (temp.) R. H. Lucas, O.B.E., M.C., and D. C. Scott, O.B.E., R.A.M.C.

*O.B.E. (Military Division).*—Col. (temp.) R. McKinlay, Capt. (temp. Major) (acting Lieut.-Col.) R. J. V. Pulvertaft, R.A.M.C.

*M.B.E. (Military Division).*—Capt. (temp. Major) R. B. Robertson, R.A.M.C.

The *London Gazette* announces the appointment to O.B.E. (Military Division) of Major (temp. Lieut.-Col.) R. E. Tunbridge, R.A.M.C., and to M.B.E. (Military Division) of Capts. J. R. Bolton and J. J. Kempton, R.A.M.C., in recognition of gallant and distinguished services in Malta.

#### DEATHS IN THE SERVICES

By the death of Lieut.-Col. ALFRED ERNEST JOHN LISTER, I.M.S., on Dec. 21 at Stroud, Gloucestershire, the Service has lost a man of sterling worth. He studied medicine at St. Bartholomew's Hospital and in Vienna and passed both the London University M.B., B.S. and the conjoint examinations in 1900, held the Brackenbury Scholarship in Surgery and took the F.R.C.S.Eng. in 1902, and in the same year was placed first in the entrance examination for the Indian Medical Service. At the end of the Netley Army Medical School course he gained prizes in hygiene, surgery, and clinical medicine. Early in his career in India Lister saw active service in East Africa and Somaliland and gained a medal and clasp, and he was also on service during the war of 1914-18. He next entered the civil department of the I.M.S. and worked in various stations until he rose to be ophthalmic surgeon to the King George's Medical College at Lucknow when that school was opened. There by his sound professional knowledge and unassuming manner he gained the respect and affection of his colleagues, though he was handicapped by poor health, which led to his early retirement in March, 1920, before which he was appointed Hon. Surgeon to H.E. the Viceroy of India. For eight years he wrote the ophthalmic section for the *Medical Annual*. After his final return to England he settled in Bristol and was appointed honorary consulting surgeon to the Bristol Eye Dispensary and did some consulting practice, though still far from being robust in health; once more he gained the respect of his colleagues. He will be much missed by his many friends and admirers. Latterly he gave up his work in Bristol and went to live at Stroud. His wife and a daughter survive to mourn his loss.

## Universities and Colleges

#### UNIVERSITY OF OXFORD

In a Congregation held on Dec. 18 the following medical degrees were conferred:

D.M.—P. M. F. Bishop.  
B.M., B.Ch.—J. M. Hastings, A. I. M. Neill, W. B. Jack, R. H. M. Baines, J. V. Garrett, S. J. G. Spencer, R. W. Fynn, B. I. Johnson, J. Evans, D. W. K. Kay, F. I. Flint, W. L. B. Leese, G. I. M. Swyer, J. L. Insley, I. R. Silliman, Marcia I. P. Harvey.

No. 51

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 25.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) Ireland and Wales (London included); (b) London (administrative county); (c) Scotland; (d) Eire; (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths (second last line), for the week and those for the corresponding week last year, for: (a) The 126 great towns in England and Wales (including London); (b) London (administrative county); (c) The 16 principal towns in Scotland; (d) The 13 principal towns in Eire; (e) The 10 principal towns in Northern Ireland.

A dash—denotes no cases; a blank space denotes disease not notifiable or no return available.

\* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

## EPIDEMIOLOGICAL NOTES

## Discussion of Table

In England and Wales infectious diseases continue to decline in incidence, notifications of acute pneumonia being down by 514, of whooping-cough by 156, of scarlet fever by 150, of diphtheria by 52, and of dysentery by 37.

Deaths from influenza in the great towns dropped to 690 (and in the week ending Jan. 1 to 464). There were 80 influenza deaths in London, 25 in Manchester, 25 in Sheffield, and 24 in Liverpool.

The lowered incidence of scarlet fever occurred mainly in the North, and also in London which recorded a drop of 58 cases. Notifications of pneumonia were down by 101 in London, and by 146 in Lancashire; in contrast to the general trend there was a rise in Yorks West Riding of 35 cases. Measles fell to a new low level, the largest returns being Lancashire 43, London 36, Durham 34.

The notifications of dysentery, though the lowest for over six months, were still relatively high. The chief centres were London 29, Lancashire 15, Kent 10, Essex 9.

In Scotland the only changes of note in the incidence of infectious diseases were rises in acute primary pneumonia 74, and dysentery 22. In Edinburgh notifications of dysentery rose from 20 to 54. The increase in pneumonia was in the western area.

## Influenza

The graph below shows a comparison of the deaths recorded in the large towns during the present outbreak with those in the three largest recent epidemics. The shapes of the curves of the completed epidemics are similar—a rapid rise to a maximum and an equally rapid fall; the four outbreaks have approximately the same rate of increase, although the heights of the maxima vary. The most notable feature so far of the present

outbreak is that the rise began some weeks earlier than in recent epidemics. It remains to be seen whether the present epidemic will follow the usual course and disappear during what normally would be the height of the influenza season, or whether the trend will display some secondary rise.

## Typhus in Naples

It has been reported that a rapid increase in the number of cases of typhus has occurred in Naples during the first week

of this year. The new cases have been estimated to be almost 100, and steps are being taken to prevent a major outbreak among the civil population. No case has occurred among Army personnel.

### The Week Ending January 1

The returns of the notifications of infectious diseases during the week in England and Wales included: scarlet fever 2,029, whooping-cough 1,509, diphtheria 578, measles 546, acute pneumonia 1,997, cerebrospinal fever 73, dysentery 89, paratyphoid 5, typhoid 7. In the great towns 464 deaths were attributed to influenza.

## Medical News

Dr. Geoffrey Marshall, O.B.E., F.R.C.P., physician to Guy's Hospital and Brompton Hospital, has accepted the invitation of Sir Walter Womersley to act as an honorary consulting physician to the Ministry of Pensions.

The Eugenics Society at its meeting on Tuesday, Jan. 18, in the rooms of the Royal Society, Burlington House, Piccadilly, W., will debate the proposition "That the programme of social security set out in the Beveridge-report should be supported on eugenic grounds." Lord Horder will take the chair at 5 o'clock.

The National Council for Mental Hygiene has arranged a course of twelve lectures on "The Psychology of Frustration and Fulfilment in Adolescence" to be given in Caxton Hall, Westminster, S.W., on Tuesdays at 5.15 p.m., beginning on Jan. 18. Tickets for the course (£1; single tickets 3s. 6d.) may be had from the Secretary of the Council, 39, Queen Anne Street, W.1. The lectures are specially addressed to those with social and educational interests, and four of the lecturers are headmasters or headmistresses. The first three lectures, by Dr. J. A. Hadfield, are on "The Psychology of Adolescence."

The following meetings of the British Institute of Radiology will take place in the Reid-Knox Hall, 32, Welbeck Street, W.1, at 2.30 p.m.: Friday, Jan. 21, meeting of medical members. Saturday, Jan. 22, ordinary meeting at which the following papers will be read: "Intra-cavitary Radium Techniques for the Treatment of Carcinoma of the Cervix Uteri," by G. J. Neary, Ph.D.; "The Combination of Gamma- and X-ray Therapy in Carcinoma of the Cervix Uteri," by B. Sandler, M.D. Gynaecologists interested in these subjects are cordially invited to attend.

The next meeting of the Biochemical Society will be held at the British Postgraduate Medical School, Ducane Road, Hammersmith, W.12, on Saturday, Jan. 22, beginning at 11.15 a.m. Luncheon (on notification) at 1 p.m.

At a sessional meeting of the Royal Sanitary Institute to be held on Wednesday, Feb. 9, at 2.30 p.m., at 90, Buckingham Palace Road, S.W.1, Mr. W. McAuley Gracie, director of infestation control, Ministry of Food, will open a discussion on rodent infestation. Members and others proposing to attend this meeting are asked to notify the Secretary of the Institute by Jan. 28.

The eighth annual medical conference of the Ex-Services Welfare Society will be held at the Waldorf Hotel, Aldwych, W.C., on Tuesday, Feb. 8, under the presidency of Lord Horder. The proceedings open at 10.30 a.m., and the medical aspect is likely to loom largely in the discussion. This conference will be followed on Feb. 11 by a meeting convened by prominent industrialists and trade union leaders.

The seventeenth annual meeting of the Association of Clinical Pathologists will be held in London at Guy's Hospital on Friday and Saturday, Jan. 28 and 29, beginning each day at 9.15 a.m. A full programme of short papers has been drawn up for the morning sessions. On Friday afternoon there will be demonstrations followed at 4.30 p.m. by the presidential address by Dr. A. F. Sladden on "The Significance of the Laboratory." The honorary secretary is Dr. W. H. McMenemey, Royal Infirmary, Worcester.

Dr. A. B. Lindsay, medical officer, Indian Tea Association, has been appointed O.B.E. (Civil Division) for services in connexion with the Burma Campaign, May 21, 1942, to June 20, 1943.

The new address of the Central Council for District Nursing in London is 25, Cockspur Street, S.W.1.

Coloured labels will in future denote the various strengths and kinds of insulin: 20 units per c.cm. will have a buff label; 40 units a blue, and 80 units a green. The same colours will be used in combination with pink for protamine-zinc-insulin, and in combination with orange for globin insulin.

After an interval of four years the annual meeting of French gynaecologists was held on Oct. 16 in Paris, where the French Society of Gynaecology met on Oct. 10.

In September there was an epidemic of poliomyelitis in Amsterdam, 66 cases of which had originated abroad.

## Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (Room 9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE No.—B.M.A. and B.M.J.: LUSTON 2111.

TELEGRAPHIC ADDRESSES—EDITOR, *Atiology* Westcent, London; SECRETARY, *Medisera* Westcent, London. ADVERTISEMENTS, *Articulate* Westcent, London.

B.M.A. SCOTTISH OFFICE: 7, Drumthugh Gardens, Edinburgh.

### ANY QUESTIONS?

#### Clinical Estimation of B.M.R.

Q.—Is there any method of estimating the basal metabolic rate clinically? I seem to remember hearing of a formula which depended on the estimation of the pulse rate and systolic and diastolic blood pressure. Can you tell me what the formula is, how it is carried out, and whether it is of value in estimating the progress of a case of hyper- or hypo-thyroidism?

A.—There are several ways of estimating the B.M.R. without actually measuring it. The best-known is that of Read and Barnett. Where P.R. = pulse rate and P.P. = pulse pressure, the Read and Barnett formulae are: for men, calories per sq. metre per hour 
$$= \frac{P.R. \times P.P.}{200} + 27$$
; for women, 
$$= \frac{3 \times P.R. \times P.P.}{700} + 24$$
. In order to convert these figures into B.M.R., they must be divided by the normal calorie production per sq. metre per hour, as given in Du Bois's chart:

Age	Males	Females
14-16 .. .. .	46 .. .. .	45 .. .. .
16-18 .. .. .	43 .. .. .	40 .. .. .
18-20 .. .. .	41 .. .. .	38 .. .. .
20-30 .. .. .	39.5 .. .. .	37 .. .. .
30-40 .. .. .	39.5 .. .. .	36.6 .. .. .
40-50 .. .. .	38.5 .. .. .	36 .. .. .
50-60 .. .. .	37.5 .. .. .	35 .. .. .
60-70 .. .. .	36.5 .. .. .	34 .. .. .
70-80 .. .. .	35.5 .. .. .	33 .. .. .

This method has some use in checking the progress of an individual patient. It is extremely unreliable for comparison between one patient and another.

Bartlett's method depends upon the breath-holding ability or duration of voluntary apnoea (D.V.A.). A person of normal B.M.R. is said to be able to hold his breath 1.8 to 2 times as long after inspiration as after expiration. In thyrotoxic patients the D.V.A. in both circumstances is reduced, but especially after inspiration.

D.V.A. In. This method  
There is therefore a reduction in the ratio  $\frac{D.V.A. In.}{D.V.A. Ex.}$

is so inaccurate that it is of no value except as a slight indication of an abnormal trend. Almost as unreliable is the "pulse-pressure pulse-rate index." The P.P.×P.R. of a normal person is said to lie between 2,880 and 3,000. It is probably true that the greater the deviation from these figures the greater is the probability of the B.M.R. being found to be abnormally high or low, but this is all that can be said for the method.

#### Neuritis with Osteo-arthritis

Q.—A woman aged about 60, nullipara, for years has had osteo-arthritis in neck and back. Massage has recently improved this and movements are comparatively free and painless. Lately a form of neuritis (?) has developed, chiefly in the left arm and especially the hand and fingers, more particularly affecting distribution of ulna nerve. Salicylates improve matters to a certain extent only. Lini-ments are unsuccessful. After pain subsides numbness is felt followed by pain when sensation returns to normal. No swelling or inflammation. No cramp. Pulse and pressure normal. The condition is intermittent. Would further local massage improve matters.

A.—The symptoms in this case appear to be due to intermittent pressure on the cervical nerve roots as they pass through the foramina, and are not infrequently met with in slight degree in osteo-arthritis of the cervical spine. The pressure may be due to osteophytes in the vicinity of the foramen, or to narrowing of the foramina from thinning of the intervertebral disks due to the degenerative processes of advancing years, or to mild trauma. The thinning may be uneven, greater on one side than the other, or may

be associated with prolapse of the nucleus pulposus of the disk. The degree of compression is affected by posture. The absence of any mention of muscle-wasting in this case indicates that the pressure is not of a serious degree. It may be due to prolapse of a disk rather than to bony pressure. X-ray examination is desirable and should include profile and oblique views; the latter will often be found to give the clearest picture of the foramina. From the ulnar distribution of the sensory disturbances it is evident that the lesion affects the eight cervical and first dorsal roots. Sometimes the pressure is greater than the degree of bony obstruction will account for as seen in the radiograph, and it may then be due to soft-tissue changes or perivertebral inflammation, which will later go on to calcification. As the movement of the spine becomes more limited by the bony outgrowths the pain may diminish. Treatment is not very satisfactory. Massage alone is not likely to be of much service, but associated with infra-red rays or short-wave diathermy may exercise a palliative effect. A supporting collar of leather or celluloid to carry the weight of the head and limit the movements of the spine would probably give a good deal of relief, but the remedy might be regarded as a more serious inconvenience than the pain. Surgical measures have been carried out with success in severe cases. A review of the subject under the title "Nervous Manifestations in Vertebral Rheumatism" appeared in the *Reports on Chronic Rheumatic Diseases*, 1935, 1, 128.

#### Swollen Leg after Parametritis

**Q.**—In March, 1942, a married woman aged 25 had her first baby—by Caesarean section owing to obstructed labour. Severe parametritis ensued; treated with sulphonamides by mouth and intramuscularly. These were given into the left buttock and caused a good deal of pain. Convalescence was very prolonged, with white-leg on left side. This has gradually improved with massage, viscopaste bandages, etc., but the leg is still enlarged, heavy, and painful, especially thigh and buttock. There is no oedema, the swelling does not pit on pressure, and is soft and of fatty consistency. She has always had rather big, fat legs. Can anything be done for the relief of this condition?

**A.**—These cases are difficult and often disappointing to treat. The thickening of the limb will certainly be permanent. Considerable relief of pain and aching would be given by expert massage. If the circulation in the limb is seriously impaired, then an improvement could be expected by a sympathectomy. The possible response to such treatment could be tested therapeutically beforehand by injecting the lumbar sympathetic on the left side. Segments 2, 3, and 4 are the ones concerned. It should be noted that encouraging results are now being obtained by this method of treatment in the acute phase of thrombosis. The prognosis in this particular case after such a long interval is not very good.

#### Intrameatal Angioma

**Q.**—A boy aged 16 months has a small reddened area just inside the urethra. This bleeds and causes a good deal of pain on micturition. It is very resistant to treatment. Could you advise me as to treatment? The child was circumcised as a baby.

**A.**—The description suggests that the condition is a small intrameatal angioma. As it is causing trouble it would probably be unsatisfactory to see what change time would bring about. If it is small it could be "diathermized" carefully without much fear of stricture. If so extensive that contracture would be a definite hazard of destructive treatment, irradiation must be used. There are obvious technical difficulties about the use of radium here in a small child, but with some ingenuity they could be overcome.

#### Angioneurotic Oedema

**Q.**—I have a man in the middle fifties who gets the unsightly swellings of angioneurotic oedema on his lip, and I have given him a course of calcium. In severe cases an injection of adrenaline might remove the swelling, but obviously it should be used only where the swelling might cause danger to life. Is there any other treatment with any prospect of success?

**A.**—An attack of angioneurotic oedema depends upon two groups of factors: (1) an allergic sensitivity, and (2) some incident which temporarily depletes or lessens the body's supply of adrenaline. The allergic sensitivities fall into three groups: first, drugs—commonly aspirin (usually taken for colds or headaches) and phenolphthalein (in aperients); secondly, feather, down, or horsehair bedding or pillows if the swellings begin at night or in the early morning, or dust if during the day; and, thirdly, certain foods. The adrenaline-depleting factors include worries, upsets, and sudden emotions, following acute or chronic illnesses, colds, and headaches. Hence swellings usually occur when a sensitive person gets a cold or a headache and takes an aspirin; when he develops a cold or an illness and is put to bed on feathers or down, or returns to some dusty job too soon after an illness; or following a gastro-intestinal upset and large quantities of certain gruels or cocoa-egg-milk beverages are given. In the treatment of the acute attack, 5 minims

of adrenaline chloride (1 in 1,000 solution) should be given at once hypodermically, and 3 minims repeated each 1/4, 1/2, 1, or 2 hours until the swelling has gone down. Ephedrine hydrochloride, 1/2 gr., should be given every four hours at the same time. Calcium is of no value. A careful history to classify the case into drug, inhalant, or food group is essential; the use of skin tests, avoidance of indicated causes, or desensitization offer very good chances of success.

#### Hereditary Cold Fingers

**Q.**—What is the treatment of arterial spasm in hands and feet of a married woman of 29? The condition, which has been present since childhood, appears as a reaction to cold, even to mild degrees of cold in the summer. The fingers, and sometimes the whole hands, become white and numb and painful, and the only way to restore the circulation easily is by immersion in very hot water. This is complicated in very cold weather by chilblains, which usually ulcerate and take weeks to heal.

**A.**—In view of the early onset and the type of colour change the trouble should be regarded as "hereditary cold fingers" rather than Raynaud's disease. It is therefore unlikely to get more serious or to merit operative treatment, though it may well have been aggravated by wartime conditions. Cold and cold water should be avoided so far as possible. A warm room is desirable during the day, and a hot bottle or bed-socks at night. Warm clothing is essential, and the hands should be kept warm with gloves, muff, or a winter-warmer such as the "platinum pocket warmer." The skin of the fingers should be kept soft with a suitable grease, and cracks dressed with collodion or elastoplast. Drug treatment is unlikely to be effective as the disorder is basically a morbid constitutional response to cold. Calcium salts and thyroid still have their advocates, though at present nicotinic acid is in favour. It is given in a dosage of 50 mg. t.d.s., which may be increased if necessary up to 500 mg. a day.

#### U.V.L. from M.V.L.

**Q.**—What is the present opinion of the value of ultra-violet light from a mercury vapour lamp as a therapeutic agent for maintaining health at this time of year, particularly in young growing children? How often should exposures be given, and what area of the body should be exposed on each occasion? Is blondness a contra-indication?

**A.**—The value of general irradiation with U.V.R. can be ascribed to three factors: (a) vitamin D production; (b) esophylactic reaction; (c) psychological effects.

(a) To promote the first of these, which is of importance in the maintenance of health, particularly in children, the largest possible area of skin should be irradiated by exposing all aspects of the body. Suberythral treatments should be given two to four times a week. As tolerance is not rapidly established with such doses, there is need for small increments only.

(b) The lethal action of U.V.R. can be made use of to provoke inflammatory reactions in the skin which, in the presence of antigens, appear to produce the elaboration of appropriate antibodies. A first-degree reaction over approximately one-sixth of the total body skin area should be aimed at and be repeated three times a week.

(c) The psychological effect can be enhanced by using a powerful source of luminous rays in conjunction with the M.V.L. and by encouraging relaxation during the treatment.

The so-called "tonic" effect attributed to "artificial sunlight" is probably due to a combination of the above effects. Blondness in itself is not a contraindication, but the thinness of the corneal layer of the skin, coupled with the inability to produce pigments so often encountered in these subjects, often makes them more sensitive to this form of treatment.

\* Esophylactic is defined in Dorland's *Medical Dictionary* thus: "Exerting a phylactic or protective influence from within, such as that of the fluids and cells of the body."

#### Plums and Apples

**Q.**—What food value is there in plums? I believe the plum has a low vitamin C content, and it is popularly described as an acid fruit tending to irritate the gastro-intestinal tract. What are these acids? Are they harmful in any way, and what nutritional virtue is there in this widely distributed fruit? Incidentally apples are also lacking in vitamin C—with the exception of Bramley seedlings—and this raises the question of the nutritional value of the familiar mixture of plum and apple in pies and in jam.

**A.**—Fortunately we still live on food, and not on vitamins. Most of us eat plums and apples because they have a pleasant and refreshing taste—in other words, because we like them. It is true that they contain very much less vitamin C than some other fruits, but this is no reason why we should scorn them. At the present time all foods which give flavour and variety to meals are of tremendous importance. Every housewife knows this and she rightly prizes such foods.

There is no evidence that plums, eaten in moderation, do the slightest harm to the majority of people. They may cause gastro-

intestinal irritation in a small number of persons; but what food is free from this objection? Experiments on healthy people showed that the amount of faeces passed when a large quantity of plums was eaten was no greater than when the diet contained no fresh fruit at all.

## INCOME TAX

### War Damage Claim—Assessor's Fee

A. F. lost some professional books, domestic furniture, and clothing by enemy action. The claim made has been accepted by the Board of Trade. A fee of 5% of the amount has been paid to the assessor. Can this be treated as an allowable deduction for income-tax purposes? He is assessed under Schedules A and E.

\* If A. F. is required to replace and use the professional books for the purposes of his employment—which, however, is apparently not the case—he can claim to deduct a proportion of the assessor's fee. Otherwise no claim can be made—he is in the position of a private citizen who has had to incur a personal expense.

### Cost of Cars

"RURAL'S" husband is in the R.A.F. and she is running the practice, using two old cars owing to the impossibility of buying a new one. Is she entitled to the 20% allowance for depreciation on both cars?

\* The question is governed by Rule 6 applicable to Cases I and II, Schedule D, which provides for a "deduction . . . representing the diminished value by reason of wear and tear during the year of any machinery or plant used for the purpose of the trade . . ." (This provision was later extended to professions.) If both cars are in fact used the allowance applies to both, and presumably will be based on the standard 20% of the written-down value.

### Military Service Expenses

J. M. H. incurs certain expenses by way of subscriptions to associations and for professional literature. He has claimed to deduct the amount from his R.A.M.C. pay and has been refused.

\* Official pay is chargeable to income tax under Schedule E, and expenses to be allowable must be wholly, exclusively, and necessarily incurred in the performance of the official duties. Such expenses as those indicated are not regarded as necessary in the performance, etc. (however desirable as a means of preparation therefor), unless the subscriptions, etc., have to be paid to comply with a condition of the employment. We fear that J. M. H. has no alternative but to accept the position.

### Assistant—Car Expenses

W. G. is an assistant receiving an allowance for the use of his own car. This brings his gross receipts over £600. Will that exclude him from the new system of tax deduction which comes into operation next April?

\* The £600 limit in the Income Tax (Employments) Act, 1943, applies to "emoluments." The amount allowed to an assistant because he uses his own car is not an "emolument" but merely the refunding of expenses incurred or accruing, and would not therefore be taken into account in dealing with the £600 limit. The way in which the limit works is that individuals whose emoluments exceed £600 are excluded, but it is to be inferred from statements in the House of Commons that in fact the limit will be abolished and will not operate in April next.

## LETTERS, NOTES, ETC.

### What is a Yawn?

Dr. B. H. KIRKMAN (St. Mary Cray, Kent) writes: The answer to this question (Nov. 20, p. 664) is in my opinion not altogether satisfying. Your correspondent considers that oxygen lack is the causal factor, but there is very little evidence that cerebral anoxia is operative in conditions under which physiological yawning occurs. It is much easier to alter the carbon dioxide content of the circulating blood under such conditions than the oxygen content. Further, yawning usually takes place under conditions favouring the accumulation of CO<sub>2</sub>—e.g., after sleeping or in stuffy lecture halls. The accumulation of CO<sub>2</sub> in such conditions provides the necessary pre-disposition to yawning, while the example of others constitutes a precipitating factor. If CO<sub>2</sub> accumulation is the cause of yawning there is no need to postulate a depressant action on the upper levels of the respiratory centre. The direct stimulant action of CO<sub>2</sub> on the basal centres (respiratory, vomiting, vasomotor) is well known, through the work of Dale and Evans and others. It is well established, as your correspondent points out, that anoxia produces depression of cerebral activity, and it is equally true that oxygen intoxication produces epileptiform convulsions (Paul Bert and

J. B. S. Haldane); but both of these phenomena occur well outside the physiological range of oxygen tensions. There is, so far as I am aware, no evidence to suggest that under normal conditions cerebral anoxia sufficient to cause definite depressive or release phenomena can occur. Your correspondent states that it is difficult to see any connexion between yawning in animals as part of an emotional reaction and yawning occurring in man and dogs under conditions of boredom. It is well known that a part of the emotional response in animals is an alteration in the rate and depth of breathing. Is it not possible that yawning in the "dilemma" situation in dogs is due to reduction of the respiratory output of carbon dioxide?

The importance of yawning in practical medicine is slight, but the discussion of its mechanism and genesis brings up the very important question of the excitability of the central nervous system in relation to gaseous tension and its bearing on the phenomena of epilepsy, tetany, ether clonus, post-encephalitic Parkinsonism, and catatonic schizophrenia. In epilepsy it has been shown that carbon dioxide exerts a depressant action on the cerebral cortex (Hill), and that its removal by overbreathing facilitates the onset of an epileptic fit. There is, so far as I am aware, no more experimental evidence to suggest that variations in the supply of oxygen to the brain are a causal factor in yawning than in epilepsy.

In conclusion I would point out that your correspondent does not mention one of the most consistent examples of yawning—namely, that which occurs immediately after the intravenous injection of pentothal and amytal. This response is so rapid that it cannot be attributed to any alteration in the gaseous balance and must be considered to be an example of a release phenomenon such as your correspondent envisages.

### Relief of Thirst

Col. E. C. HODGSON, I.M.S. (ret.) writes: Having read your review of Dr. Macdonald Critchley's book *Shipwreck Survivors* (June 12, p. 726) and realizing, in part at least, the terrible torture of thirst in the Tropics, after 35 years in various parts of the Tropics—India, the Sinai Desert, and above all a summer in the Jordan valley with no protection, even of a tent, from the sun in 1918—may I mention the greatest immediate relief that can be obtained from inordinate thirst? The body should be soaked in a bath or the sea, and within 5 minutes the inordinate thirst vanishes to a mere desire for a small glass of fluid, and the lips and tongue become moist again, instead of sticking to the teeth and roof of one's mouth. I see in your review that Dr. Critchley mentions a 50% survival rate after 32 days' almost entire submersion; I suggest *because* of almost entire submersion. Medical field research work in the open on malaria, plague, and cholera during the hot weather in India, etc., where to drink the local water supplies would soon make one a casualty, has at least shown what thirst can mean; and the amazing sensation of relief that quickly follows immersion of the skin in water shows where the cry for fluid comes from in the body.

### Treatment of Paronychia and Subungual Sepsis

Dr. W. H. PALMER (Hayle, Cornwall) writes: Until now, among the most discouraging of minor septic ailments have been cases of paronychia with commencing subungual sepsis. No matter what was done the condition almost always spread further and further under the nail, and it was lucky if one had to do no more than remove the nail to prevent or cure even deeper or wider mischief. It meant also to the manual worker a period of disability generally adding up to weeks. The trouble usually starts with a crack or tear in the cuticle, and generally in the corner, which gets red and inflamed, and then a bead of pus can often be expressed by gentle pressure from under its edge. For the last year I have been treating these cases by the following method, and have not had to remove a nail, and only rarely incise anywhere. The condition has been cured rapidly, sometimes in only a few days. The fact that pus had really been under the nail is proved by the destroyed area of nail showing as it grows up to view.

Attention to the following details is important, but the whole process takes only a few minutes. (1) The cuticle is gently raised off the nail by a blunt, flat-pointed instrument, or back edge of a scalpel near its point. (2) Gentle pressure is tried to see if pus comes, which is then wiped away with cotton-wool. (3) Pulv. sulphanilamide-P is gently pressed under the raised cuticle edge as deep as it will go in without causing real pain, and a little heap left all round the cuticle edge. This takes less than half a tablet. (4) A narrow piece of elastoplast gauze is then put over that heap of powder and round the digit, leaving top and bottom edges free. (5) The whole must be kept quite dry. (6) The above process is repeated daily at first, and later at intervals of two or three days, until no inflammation is visible. (7) If obvious pus is there which doesn't come out from under the cuticle a small incision may be necessary. The comfort and speedy cessation of pain or throbbing are remarked on by the patient, generally within 24 hours. Possibly sulphanilazole would do as well, or even better, but the results with sulphanilamide-P have been so good that I have not tried anything else.

LONDON SATURDAY JANUARY 22 1944

## EMPHYSEMA OF THE LUNGS\*

BY

RONALD V. CHRISTIE, M.D., D.Sc., F.R.C.P.

*Professor of Medicine in the University of London: Physician to St. Bartholomew's Hospital*

### PART I

Emphysema is a progressive and incapacitating disease, and, although its description is precise and dogmatic in most textbooks, the majority of cases diagnosed on the post-mortem table are not recognized during life, many experienced physicians admitting that they do not understand the diagnosis of emphysema, except in its later stages. Even the term "emphysema" is ambiguous: in these lectures it is used to mean chronic vesicular or hypertrophic emphysema of the lungs, it being understood that acute emphysema, senile emphysema, and localized emphysema are probably separate and distinct entities. I will discuss first the nature of the lesion as shown by observation of the living subject as well as by necropsy.

#### Nature and Extent of the Enlargement of the Lung

The most obvious changes are in the alveoli, the walls of which appear stretched, thin, and in many places ruptured, so that the septa between adjacent alveoli may be reduced to small projections. It has been claimed that the rupture of the alveolar wall begins at the so-called alveolar pores, but whether or not this is true seems to be of little significance. Of much greater importance is the effect of this destructive process on the air sacs of the lung and on the volume of the lung as a whole, and several changes have been described:

- (a) The normal lung lobule or air sac consists of an alveolar duct opening into the atrium, around which are placed the alveoli, and in health there is a sudden transition from narrow alveolar duct to wide atrium, so that the inspired air may be thrown as a jet into the more remote parts of this terminal segment. These lobules have been studied in detail by means of serial sections and of specimens injected with celloidin, and in emphysema it has been shown that the lobule is distorted and sometimes distended (Beitzke, 1925; Countz and Alexander, 1934). The alveolar duct is dilated and funnel-shaped, so that air is no longer thrown into the atrium as a jet. If it could be shown that this jet of air does in fact serve a useful purpose in ventilating the lobule, it would be reasonable to suppose that this function would be impaired in emphysema.
- (b) As the alveolar walls become thin and disappear the air sacs may lose their honeycomb structure and so be deprived of their supporting framework; this is especially true on the surface of the lung, where large bullae may be formed. Provided that the airways on these lobules and bullae remain patent, one would expect that very little pressure would be required to deflate them, and once deflated very little traction would be required to distend them. In other words, it might reasonably be supposed that these flimsy lobules could be more distensible than those lobules which had not lost their supporting framework of alveolar septa.

- (c) Another important sequel to this dilatation of the air sacs is the increase of the volume of the lungs as a whole, which is usually

obvious on the post-mortem table: the large fluffy lungs strongly suggest that during life there is an increase in the amount of air they contain. This amount can be measured, and early in the present century several investigators showed that there is usually an increase in the residual air in emphysema. But the residual air is the amount of air left after a forced expiration, and it is well known that patients with emphysema may have great difficulty in forcibly emptying their lungs. A more significant measurement is the amount of air in the lungs at the end of an ordinary quiet expiration; for this is their true air content during life, while the residual air is the result of respiratory gymnastics and may have no relation to the normal size of the lungs. In the accompanying Chart are shown the results of measurements of the lung volume and

Chart showing the lung volume and its subdivisions in emphysema. Cases are arranged from left to right in order of severity of dyspnoea.

its subdivisions in 8 patients suffering from emphysema; it is clear that the amount of air in the lungs was increased in all of them, although only very slightly in several. For instance, the increase was slight in the case of S. H., and yet he was an evident case of emphysema, with dyspnoea on the slightest exertion; while in C. N., a less severe case of emphysema, the volume of the lungs was greatly increased. In none of these cases was the increase ever as great as the volume of a normal lung in full inspiration. These findings have been confirmed by several investigators, and it is clear that in emphysema the lungs as a whole usually contain more air than they should, but this never amounts to more than the increase which occurs in the size of the lungs of a normal individual when he takes a breath of moderate depth. (Hurtado, Fray, and McCann, 1933; Christie, 1934; Anthony, 1936; Courmand, Lassen, and Richards, 1937.) There is certainly never evidence of true overdistension or overstretching of the lungs as a whole, and sometimes

\* An abridged version of the Goulstonian Lectures delivered before the Royal College of Physicians on March 4, 9, and 11, 1943.

in even severe emphysema there is no enlargement, but this is uncommon. On the post-mortem table the lungs seem to be greatly enlarged mainly because they do not collapse, and the microscopical appearance of gross over-distension of the alveoli must be due chiefly to destruction of the alveolar walls and the fusion of air spaces.

We can conclude from these various observations that the emphysematous lung is deformed in at least three ways. First, many lobules or air sacs are misshapen and the alveolar ducts are dilated, so that air is no longer thrown into the atrium as a jet. Secondly, the septa between alveoli may disappear, so that the supporting framework of the air sac may be lost. These air sacs or bullae then become comparable to bags of tissue paper, which are easily compressed and easily dilated. Thirdly, the amount of air in the lungs is usually increased, but this increase is not proportionate to the severity of the disease, nor is the volume of the emphysematous lung at rest ever as great as the volume of a normal lung in full inspiration. Thus, whatever may be its microscopical appearance, the lung as a whole in emphysema is not overstretched or over-distended any more than a normal lung is over-distended or overstretched when a breath of moderate depth is taken.

Changes in the lumen of the bronchi and bronchioles also occur, but these are not constant. The terminal bronchioles as well as the alveolar ducts are usually dilated, and this may extend up to the smaller bronchi, producing a picture resembling cylindrical bronchiectasis. The state of the medium and larger bronchi is, however, very variable, and depends more on the degree of bronchitis than on the degree of emphysema, although some atrophy and dilatation are usual in severe cases.

#### Elasticity of the Lung

Changes in the elasticity of the emphysematous lung were first suggested by a Fellow of our College, William Watson, in 1795. When the thoracic cage is opened on the post-mortem table the lungs do not collapse, and this alone would appear to be proof that the normal elastic recoil of the lung had been lost. However, more detailed observations on the pulmonary elasticity made by measuring the force required to inflate and deflate the lung, have given conflicting results in emphysema (Tendeloo, 1925; Loeschke, 1928; Thies, 1932). Considerable changes in the elastic properties of the lung occur after death, and the significance of post-mortem measurements of elasticity has been seriously questioned. The fact that the lungs do not collapse when the thorax is opened has been said to mean only that they are overstretched in the same way as a spring may be overstretched and yet maintain much of its elasticity. Histological study of the lungs gets us no further, as there is the same disagreement among morbid anatomists as to whether the elastic fibres are destroyed or merely overstretched; nor do the morbid appearances indicate whether loss of elasticity is an early or a late manifestation of the disease. These points are not merely of academic interest, as, if it can be shown that loss of elasticity is early and complete, many of the changes in emphysema can be explained, and for this reason I have measured the elasticity of the lung during life in three cases of pulmonary emphysema. The method used has been described elsewhere and its accuracy has been confirmed (Christie and McIntosh, 1934; Paine, 1940a, 1940b). It is based on the simple observation that the intrapleural pressure is a direct measure of the tension or elastic recoil of the lung. In emphysema the intrapleural pressure is not always negative as it is in health; even at the end of a full inspiration the intrapleural pressure may be the same as that of the atmosphere, and it is not altered when the lung is collapsed by a pneumothorax. These phenomena can only mean that the elasticity of the lung in emphysema may be entirely lost at a comparatively early stage of the disease (Christie, 1934).

It is usually assumed that any loss of elasticity is secondary to over-distension—an assumption which is unsound, as the lungs as a whole are neither overstretched nor truly over-distended. It is not generally realized that the converse is more likely to be true: the enlargement of the air sacs and the fact that this enlargement is most conspicuous at the periphery of the lung can be fully explained as being the direct result of loss of elasticity. That this is so is apparent if it is remembered that, in health, distension of the lung is maintained by traction of the chest wall and diaphragm, and this traction is counterbalanced by the elastic pull of the lungs. It follows that if

these forces are abolished, as occurs when an artificial pneumo thorax is given, expansion of the thoracic cage is to be expected as well as collapse of the lung. That considerable expansion of the thoracic cage does in fact occur while an artificial pneumo thorax is being given can be shown if the patient breathes from a recording spirometer; the air displaced into the spirometer is only about half of what is injected into the pleura, and the rest must have been utilized in expanding the thoracic cage (Christie and McIntosh, 1936). It is clear, therefore, both from first principles and from experiment, that loss of pulmonary elasticity in emphysema could be the direct cause of expansion of the thoracic cage.

Loss of elasticity could also explain the real over-distension of air sacs, with bulla formation which occurs on the surface of the lung. With loss of elasticity the expanding force is no longer equally distributed, and equal expansion in different parts of the lung should not be expected. In fact, the greatest expansion should occur where the force is applied, and this is at the surface of the lung. With each inspiration one would expect the superficial air sacs to be strained and stretched to a greater extent than the air sacs deep in the lung, and with this process going on for months and years, it is easy to understand the formation of bullae on the surface of the organ.

#### Pulmonary Circulation

Extensive changes are described in the pulmonary circulation. Many of the capillaries are torn and obliterated, and there is usually widespread atherosclerosis of the pulmonary vessels. A great deal has been said and written on the relationship of the vascular destruction to hypertrophy of the right ventricle, and although this controversy may be of importance with regard to the aetiology of cor pulmonale, it seems to be of little significance in emphysema. All are agreed that the pulmonary vascular bed is diminished in emphysema and that the work of the right ventricle may be increased, but this does not mean that the total blood flow through the lung is diminished. If it were reduced the output of the left ventricle would also be reduced, and there is evidence, which I need not describe, that this does not occur until heart failure supervenes.

The lymphatic circulation in emphysema has received but scant attention. The peripheral lymphatics may show cellular infiltration, and the characteristic pigmentation of the lung probably reflects deficient lymphatic drainage.

#### Distribution of the Lesion

To the naked eye the lesion appears to be most pronounced on the surface of the lungs, especially along the margins, where large bullae may be apparent. Under the microscope, however, it is clear that the changes we have been discussing extend throughout the lung, although the dilatation of air sacs is most conspicuous at the periphery. Characteristic changes outside the lungs have been described. The visceral pleura is thin, flimsy, and atrophic. There is usually a moderate degree of kyphosis, involving all the thoracic vertebrae, which is in contrast to senile emphysema, in which the curvature is as a rule upper dorsal. The vertebral cartilage may be thin and compressed anteriorly, where there may be tipping of the vertebrae. Perhaps partly owing to this curvature, the ribs are widely spaced and run horizontally, and their cartilages frequently show ossification or become elongated and less elastic (Kount and Alexander, 1934).

#### Haemo-respiratory Exchange

By far the most important disturbance of function in emphysema is an inability to ventilate the blood, and this is usually apparent many years before the patient reaches the pathologist. The simplest way to measure deficient ventilation in the lungs is to analyse the arterial blood, for this is what the lungs have ventilated. This has been done on many cases with emphysema (Meakins and Davies, 1925; Peters and van Slyke, 1931; Hurtado, Kaltreider, and McCann, 1935); the accompanying Table describes the results of such an analysis in two of the patients whose pleural pressure had been measured and the elasticity of whose lungs was found to be destroyed, and in another even more severe case. These

cases have been chosen as they represent moderate emphysema, severe emphysema, and emphysema in its terminal stages. The first (I. H.) had the obvious symptoms and signs of emphysema, but under conditions of rest there was no dyspnoea and no cyanosis. He could walk around the ward, but if hurried became dyspnoeic. His haemoglobin was normal in amount

*The Arterial Blood in Emphysema. (For Methods used see Christie, 1934)*

Case	Oxygen			Carbon Dioxide				Remarks
	Capacity	Content	Saturation	Content (Whole Blood)	Content (Plasma)	p. CO <sub>2</sub> (calculated)	Alveolar p. CO <sub>2</sub>	
	Vols. %	Vols. %	%	Vols. %	Vols. %	mm. Hg	mm. Hg	
I. H.	19.4	17.5	90	51.4	62.6	47	39.3	
	21.0	19.4	92	47.2		43	38.5	
S. H.	26.4	21.6	82	53.1		83	71	Saturation 102% when breathing 100% oxygen
	28.6	22.4	78	51.1		73	68	
H. R.	20.9	15.1	72	74.5	101.7	93		{ Venous blood without stasis After venesection of 900 c.cm.
				74.1	88	90		
						84		

but only 90% saturated with oxygen, which suggests a slight impairment of oxygenation.

The second (S. H.) was a much more severe case of emphysema; he was short of breath on the slightest exertion, there was considerable cyanosis, and the changes in the arterial blood were more striking. The saturation of the blood with O<sub>2</sub> was only 80%, but this anoxaemia could be relieved by oxygen, which is characteristic of emphysema and is, of course, proof that the cause is some impairment of ventilation of the blood in the lungs. In an attempt to compensate for oxygen lack the amount of haemoglobin was increased; the oxygen-carrying power of the blood was 27 vols.%, which is equivalent to a Hb value of over 130% according to any of the ordinary standards. There was also a spectacular increase in the pressure of CO<sub>2</sub>, both in the blood and in the alveolar air. This increase in CO<sub>2</sub> in the alveoli is, as I will stress later, characteristic of severe emphysema, and is proof that the cause of the accumulation of CO<sub>2</sub> in the blood is deficient ventilation, and not any barrier between the blood and the alveolar air.

The third case has been included because it represents the most marked disturbance of haemo-respiratory exchange in emphysema which, to the best of my knowledge, has ever been described. He was a typical case of advanced emphysema, and was critically ill, with severe heart failure. The oxygen saturation of his arterial blood was 72% and the pressure of CO<sub>2</sub> lay between 84 and 93 mm. Hg. Not only did he show a compensatory polycythaemia but also a compensatory increase in the bicarbonate reserve, without which he would have suffered a fatal acidosis. This combination is often found in severe cases of emphysema, and in my opinion is another illustration of how confusing is the practice of defining acidosis or acidemia as a decrease in the alkali reserve or CO<sub>2</sub>-combining power, and defining alkalosis or alkalemia as an increase in the CO<sub>2</sub>-combining power. In emphysema the alkali reserve or CO<sub>2</sub>-combining power may be raised to over 110 vols.%, with a corresponding reduction in the plasma NaCl, and yet the patient, far from having an alkalosis, is hovering on the brink of acidosis. In the van Slyke classification of acid-base balance and its disturbances this condition would be called a compensated gaseous acidosis, which is obviously what it is in spite of the alkali reserve.

These are the important changes in the blood which occur in emphysema: in severe cases there is gross deficiency in both oxygen absorption and CO<sub>2</sub> elimination, and in the milder cases this deficiency is manifest only when the demands of metabolism are increased by exercise. The defect appears to lie in deficient ventilation of the alveoli rather than in any barrier between the alveolar air and the blood.

### Cause of Impaired Haemo-respiratory Exchange

Many explanations of the impairment of aeration of the blood in emphysema have been given, but most of them are based only on conjecture and can be shown to be unsound:

(a) It has been suggested that the respiratory musculature is incapable of properly ventilating the lungs for the same reasons that the vital capacity and chest expansion are diminished; but the blame cannot be placed on the muscles of respiration, as the amount of air drawn into the lungs with each breath and during each minute is normal or even increased in emphysema. Diminution in vital capacity cannot therefore be the cause. The fault must lie in the lungs, as for some reason the air which is inspired does not properly ventilate the blood.

(b) It is obvious that the defect cannot be due to any barrier to the transfer of gases across the pulmonary epithelium, as if this were the cause CO<sub>2</sub> would increase in the blood but not in the alveoli. The fact that changes in the blood are associated with proportionate changes in the alveolar air rules out any suggested possibility of a barrier.

(c) An explanation which is commonly given is that with so many alveoli destroyed there is insufficient functioning lung. Many investigations of haemo-respiratory exchange have been made in patients with pneumothorax, pneumonectomy, and other conditions in which the amount of functioning lung is greatly reduced. Impairment of gaseous exchange, mainly affecting the absorption of oxygen, is found when the reduction in the volume of the lungs is so extreme that the tidal air or the amount of air breathed is diminished (Christie, 1936; Courmand and Berry, 1942). This is in contrast to emphysema, in which there is no diminution in the amount of air inspired and the elimination of CO<sub>2</sub> is impaired to the same extent as the absorption of O<sub>2</sub>. "Diminution of the amount of functioning lung" or "diminution in the respiratory surface" cannot therefore explain the changes observed.

(d) Diminution in pulmonary blood-flow has been suggested as the cause. I have already stated that no such diminution occurs until heart failure supervenes. The amount of air entering the lungs is normal or even increased, so any diminution in pulmonary blood-flow would naturally lead to over-ventilation of the blood and not under-ventilation.

(e) A much more reasonable explanation, and one which is widely accepted on the Continent, is that the air sacs are not properly ventilated—partly because they are big, but mainly because the alveolar ducts are distorted (Beitzke, 1925; Kountz and Alexander, 1934). It is true that in emphysema the sudden transition from narrow alveolar duct to wide atrium is lost in many of the air sacs; and it is claimed that the air is no longer thrown in as a jet and the more distant alveoli are therefore not properly ventilated. This has been named the "stratification" theory, so called because it assumes a gradient of ventilation in the lobule, those parts next to the alveolar duct being over-ventilated and the parts further away being under-ventilated. This sounds reasonable, but the validity of this theory of stratification obviously depends on the assumption that in health there must be circulation of air in the air sacs and alveoli, and that diffusion alone is insufficient to maintain adequate exchange of gases in the lobules. The diffusion of gases is governed by well-defined laws, and it can be calculated that, even if the lobule is 1 cm. in diameter, diffusion alone would ensure the transport of gases across the alveolar space with a gradient of less than 1 mm. of Hg. The details of this calculation, together with other evidence which casts doubt on the stratification theory, have been published elsewhere, and it would appear that defective ventilation of the lobule cannot account for the extreme impairment of gaseous exchange observed in emphysema, in which the pressure of CO<sub>2</sub> may be raised by 30 or 40 mm. of Hg (Christie, 1939).

(f) Increase in the volume of the lungs has been suggested as the cause of impaired ventilation, on the assumption that it is more difficult to ventilate a large room than a small one. It is certainly true that in emphysema the amount of air remaining in the lungs at the end of an ordinary expiration is usually somewhat increased, and this explanation may therefore appear reasonable. Physiologists have paid but little attention to the significance of the amount of air in the lungs,

and I will not discuss the various factors involved. It can be said, however, without fear of contradiction, that, provided ventilation is distributed evenly throughout the lungs and alveoli, an increase in lung volume can in no way impair haemo-respiratory exchange. Increase in lung volume could only diminish the fluctuation in the concentration of alveolar gases which occurs during inspiration and expiration. The simile of the large and small room is fallacious, for if you have the same number of people in the small room as in the large room, and the same amount of air used for ventilation, there will be no significant difference in the atmosphere of the two rooms. In any case, increase in lung volume when it occurs is essentially due to increase in the size of individual lobules, and, as I have already stated, diffusion alone could maintain adequate gaseous exchange in a lobule much larger than the average size in emphysema.

(g) An increase in the respiratory dead space has been suggested as the cause of impaired haemo-respiratory exchange, but there is ample evidence that any increase in the anatomical dead space—i.e., the space occupied by the respiratory passages down to the bronchioles—is too small to be of practical significance (Hoover and Gammon, 1915). I will not enter into a discussion on the meaning of the physiological dead space. Most physiologists will agree that those who claim an increase in physiological dead space in emphysema are merely stating in a complicated way that the distribution of ventilation is unequal. In the normal individual the distribution of ventilation is remarkably even throughout the lungs, and consequently samples of alveolar air taken after expirations of varying depths are more or less uniform in composition. This is not the case in severe emphysema: the deeper the patient expires the higher is the  $\text{CO}_2$  content and the lower is the  $\text{O}_2$  content of the "alveolar air," and these patients show the apparent paradox that, although the amount of air inspired is normal or even increased, the alveoli are under-ventilated. That part of these lectures which deals with the analysis and interpretation of these observations is discussed elsewhere; the conclusion which has been drawn from them is that much of the inspired air is deflected to the enlarged air sacs and bullae, the walls of which are avascular and which are therefore not in contact with the pulmonary circulation. This wastage of ventilation on functionless air sacs cannot be defined as wastage due to increase in physiological dead space, as there is nothing physiological about an emphysematous bulla. Nor can it reasonably be called increase in anatomical dead space. If a definition is wanted I would prefer to give as the cause of impaired haemo-respiratory exchange in emphysema the formation of a pathological respiratory dead space, consisting of bullae and other air sacs which are not in contact with the pulmonary circulation. In very severe emphysema it is possible that all of the inspired air enters this pathological dead space, so that haemo-respiratory exchange would depend mainly on diffusion. In less severe cases it is probable that only some of the inspired air is wasted in this way.

#### Dyspnoea

The cause of dyspnoea in emphysema is clearly stimulation of the respiratory centre by the  $\text{CO}_2$  retained in the blood. Under resting conditions the patient with emphysema either can just get rid of the  $\text{CO}_2$  he is forming or, if not, he can compensate by increasing his alkali reserve; and in either case he is not dyspnoeic, because the acidity of his blood is normal. When he exercises, however, he cannot eliminate the extra  $\text{CO}_2$  he forms; a gaseous acidosis occurs, and dyspnoea must result. In the absence of bronchospasm there is no orthopnoea, because there is no pulmonary congestion, which is the cause of true orthopnoea.

(Part II, concluding the lectures, will appear in next week's issue, with the list of references.)

The urgent need to prepare a new generation of Jewish physicians, especially in view of the tragic extermination of European Jewry, was urged by Prof. Bernhard Zondek of the Hebrew University when he recently opened the annual conference of the Palestine Jewish Medical Association. The conference was devoted mainly to discussing the problem of establishing a world-wide organization of Jewish physicians with its chair in Palestine. It is planned to issue an English edition of the Jewish medical journal *Harefuah* to be distributed among Jewish doctors throughout the world.

## SUPERVISION OF PREGNANT WOMEN IN FACTORY EMPLOYMENT

BY

J. V. O'SULLIVAN, F.R.C.S., M.R.C.P., M.R.C.O.G.,  
M.D., M.A.O.

*Obstetric Surgeon, City of London Maternity, Queen Mary's, and  
Beaumont Memorial Hospitals*

AND

L. B. BOURNE, M.R.C.S., L.R.C.P., D.A.

*Works Medical Officer*

The employment of pregnant women has become of vital importance at the present time, and we think it will be of interest if we record our experience in a factory concerned with a specialized industry (light engineering) in which an ante-natal clinic has been established to supervise women employees. It is realized that the figures are small, but we feel that the time has come for a very careful investigation into all factors connected with pregnancy among industrial workers. To obtain sufficiently large figures from any one industry might take so long that much of the value of the ultimate findings would have lost their importance.

We have attended a total of 178 pregnant women, who have come from North-East London. Of these, 90 have been delivered in the first year—82 in hospital and 8 at home—and the greater number have been followed up after delivery to assess any ill effects. All were employed in such work as soldering, welding, assembling small machine parts, etc. Their heaviest jobs were operating capstan lathes and drills. Some of the workers are engaged in a specialized form of assembly in workshops where the temperature at any time is roughly  $10^\circ$  Fahrenheit higher than normal. A full-time factory medical officer is always at call for emergencies, and there is an adequate staff of State-registered nurses (a proportion of whom are certified midwives), who undertake to deal with normal emergencies of industrial medicine.

#### The Ante-natal Clinic

With the ever-increasing number of pregnancies being reported to the surgery nurses, it was decided—after consultation—that the most satisfactory arrangement would be to set up an ante-natal clinic within the factory. Women reported their pregnancy to the surgery nurses, to the medical officer, to the welfare department, or direct to the midwife in charge of the clinic. Arrangements were then made for their examination and confinement. If they wished to be confined at a hospital—and the larger proportion did—an appointment was made for them, and they were given a covering letter when they went to book at the out-patient department. Having booked a bed and made financial arrangements with the hospital almoner, the women then continued to receive routine examinations at the works ante-natal clinic until such time as they left their employment. One of us (Mr. J. V. O'Sullivan) visited the factory at fortnightly intervals in order to examine these cases. Later, the scheme was enlarged to include the treatment of gynaecological cases. Women from all the factory departments have taken advantage of the scheme, and they include clerical and canteen staffs and cleaners, as well as the factory bench operators referred to above.

Wherever it was deemed necessary, lighter work or shorter hours were advised, and the management put such medical suggestions into immediate practice. We consider this to be of great importance in the supervision of women's health in factories.

We first made a general rule that all patients should cease work at the fifth month of pregnancy, but as time went on we found that most of them wished to continue at their work in later pregnancy, and as they showed no evidence of fatigue or ill-health we permitted them to do so under the special supervision provided. It would appear that so little is the health of experienced workers affected by pregnancy that they continue to work on night shifts without any apparent strain.

It was felt, however, that this was inadvisable, and it is therefore no longer permitted when the patient is known to be pregnant.

All pregnant women, of course, had the advantages of the extra nourishment and vitamins distributed through the Government scheme. The local health authorities have co-operated by allowing us to set up a distributing centre for vitamins and cod-liver oil within the factory. Many women previously complained that they were unable to take full advantage of the Government scheme on account of the time they spent (with consequent financial loss) in travelling to the various centres. The nursing staff have been able to find cases of pregnancy earlier than if these women had reported to outside ante-natal clinics in the usual way.

The management of the firm has permitted secretarial assistance sufficient to arrange for all appointments, admissions, etc., into any hospital chosen by the woman. This is, of course, of particular value in time saved, for she would otherwise have to go and arrange bookings and appointments herself.

### Preparatory Routine

At the ante-natal clinic the usual routine investigations, such as blood pressure, urine testing, etc., were carried out. Originally, routine Wassermann tests were done at the first visit. It was found that this was not wholly satisfactory, as the question of future infection at any given time had to be considered. It was not practicable to carry out a routine Wassermann test at each subsequent visit, and so the present policy is to leave it until there is the slightest suspicious clinical sign. It is the custom to make a routine Wassermann test in all cases of toxæmia of pregnancy (or in any case of an unmarried pregnant woman). In view of the present abnormal living conditions and the breaking up of normal home and family life, the greatest possible vigilance must be exercised by all in attendance on ante-natal patients. We have had only one positive reaction in 43 cases to date. Clinical signs had suggested this, and the W.R. confirmed the necessity for treatment. We would stress the absolute necessity that the test be done by pathologists who have specialized in this field. All our pathological investigations and x-ray examinations are carried out at one of the large general hospitals.

We feel, at the end of the first year, that this clinic has been of great assistance to the working pregnant women in the factory. It has saved them time and money, and many working hours.

A pregnant patient generally reports to the surgery in the unit in which she is working. The sister-in-charge communicates with the sister in charge of the ante-natal clinic, and an appointment is arranged convenient to the patient and to the demands of routine of the shop in which she works. At the interview with the sister at the clinic full particulars are taken, the patient's local practitioner is informed that this patient has sought advice, and she is then booked to see the consultant at his next visit. Records are kept of all findings, and of the patient's general condition, the type of work she is doing, and her financial position. She is provided with simple instructions as to her personal care, hygiene, feeding, etc. Next a bed is booked for her at the hospital of her choice. Some hospitals prefer to see the patient once early in pregnancy, and then return her to the works clinic. Later in the pregnancy she returns to the hospital with full records as to her progress while she is under our care. After the patient is delivered, she is followed up by the department as to her general health and the possibility of returning to work, and is given information as to day nurseries in her district, etc. Co-operation from the welfare department is whole-hearted, and in this way the patient can be afforded financial assistance or can be permitted to take advantage of all schemes at present available.

### Employment Restrictions

The College of Midwives in Dec., 1940, issued a leaflet on the "Restriction of Employment of Women Before and After Childbirth." In this it suggests: (1) four weeks' rest before the expected confinement; (2) eight weeks' absence from the factory after the birth of the child. (The period permitted under the Public Health Act, 1936, is four weeks.). The College

believes that much could be done to make the position of pregnant women easier, particularly as regards financial assistance by the State. It is of interest to note that the proposals adopted at the General Conference of National Labour Organizations of the League of Nations convened at Washington by the Government of the United States of America on Oct. 29, 1919, which binds the countries that ratify it to prohibit the employment of women six weeks before and six weeks after childbirth, and to make provision for their maintenance, was never ratified by the British Government. So far as this country is concerned, there seems to be no standard laid down for the care of working women who become pregnant. The issue of the College of Midwives leaflet was advisory only, and no further steps have been taken by any of the authorities.

The Union of South Africa has dealt with this question through a Factory Act which includes provisions far beyond those in force in this country.\* In Germany, too, it appears that the Reich Ministry of Labour ensures the protection of all female workers. It prohibits the employment of pregnant and nursing mothers on jobs which might prove harmful to them. Every woman must be completely exempt from every kind of work for six weeks before and six weeks after the birth of a child. This period is increased to eight weeks in the case of nursing mothers. The nursing of children is encouraged by the granting of a paid nursing period. The law prohibits the employment of pregnant and nursing mothers on overtime, night work, and holiday work. It also extends protection against dismissal. It is a punishable offence to dismiss a woman because of pregnancy, and she must not be given notice of dismissal for other reasons from the beginning of pregnancy until four months after childbirth. Unfortunately this law was modified to apply only to women of German nationality, and with a few exceptions it did not include Poles, Jewesses, Gypsies, etc., who were working under forced labour conditions in the German factories. All they were permitted to do was to refuse to continue to work if they could prove they were likely to be confined within the next two weeks, and they were allowed freedom from employment for six weeks after confinement. It seems likely that the majority of the foreign women working in Germany worked until 8½ months pregnant. The conclusion one can draw from this is that Germany valued female labour, and particularly the breeding of healthy offspring.

At the present time there seems to be no special standard laid down for the care of working women who become pregnant, apart from the above. When pregnant women are employed it is of vital importance that they be carefully supervised by experts, and only under these conditions is it fair to allow women to continue to work in factories in the later months of pregnancy. Our experience shows that no women have come to any apparent ill-health during their pregnancy or labour from doing work in this factory. We think this point is of great importance in the present emergency, because many of the women are highly skilled in their work, which they have been doing for years. Labour wastage cannot be made good; it is a great hindrance to production, for it often takes many months before the unskilled new entrant to industry becomes relatively useful as a producer. If, therefore, women can be kept at work for a longer time in the factories without in any way injuring their health, the value to industry must be great; but the fact that working women must undertake

\* Factories, Machinery and Building Work Act of 1941 for the Union of South Africa; Chap. III, Par. 23, subsections (1) and (2):

"(1) No female shall work in a factory and no employer or occupier shall require or permit any female to work in his factory during the period commencing 4 weeks prior to the expected date of her confinement and ending 8 weeks after the date of her confinement. Provided that, if the child be stillborn, or dies before the expiration of 8 weeks after birth, the provisions of this subsection shall cease to apply as from a date fixed by an inspector.

(2) The Minister may from public moneys pay to any female who, in circumstances to be determined by him, has discontinued her work in a factory as a result of pregnancy, an allowance equivalent to her ordinary weekly remuneration, but not exceeding 25s. per week, for a period not exceeding 12 weeks, which allowance may be paid in lump sum or in such instalments as the Minister may determine: Provided that payment of such allowance may be made in respect of an additional period not exceeding 4 weeks if such female discontinued her work in a factory as a result of pregnancy more than 4 weeks prior to the expected date of her confinement."

manifold household duties, etc., after their day at the factory must also be taken into consideration.

We are not in a position to refer to the employment of pregnant women except in the special factories in which we have worked. We feel that co-ordination between employers of labour, trade unions, and Ministries should now be forthcoming, so that a general scheme for rationalizing the position of pregnant women in industry may be worked out for the whole country.

#### Analysis of Cases

TABLE I

No. of patients, 90 (68 primiparae, 22 multiparae):				
Group 1 (under 20 years)	..	10		
" 2 (21-25 years)	..	36 (31 primiparae; 5 multiparae)		
" 3 (26-30 years)	..	27 (20 " 7 " )		
" 4 (31-40 years)	..	15 (6 " 9 " )		
" 5 (over 40 years)	..	2 ( " 2 " )		

TABLE II.—Periods of Pregnancy at which the Women ceased Factory Work

Weeks of Pregnancy	Group 1		Group 2		Group 3		Group 4		Group 5		Totals
	M.	P.	M.	P.	M.	P.	M.	P.	M.	P.	
18											5
20		1		3		2					8
22			1	3		1		1	1		1
24				2		4		2			7
26				7	1			4	1		15
28		3		8	3	6	3				24
30			1	2	1	2	1				7
32		1		3		3					7
34		2	1	2	1	1	1	1			9
36		3	1	1	1		1				7
Totals	10		36		27		15		2		90

Of the series of 90 cases, 77 confinements were normal, 80 had normal pregnancies, and 87 had an uneventful puerperium. There were 7 cases of toxæmia (including 2 cases of primary hypertension), 2 cases of puerperal pyrexia, 1 case of severe anaemia (below 50%), 9 cases with haemoglobin between 50 and 60%, 38 with haemoglobin between 60 and 75%, and 42 with haemoglobin above 75%. Abnormal labours comprised 1 Caesarean section and 4 forceps; premature labour—2 premature (1 stillbirth of 3 lb.) and 2 breeches. Breast-feeding was established in 77 cases out of a total of 90.

#### Conclusions

Ante-natal clinics in factories where pregnant women are employed are very advisable under present conditions.

Where insufficient numbers in any one factory render this impossible, clinics to cover groups of factories in an area might be established.

Under medical supervision many women can do suitable work to an advanced stage of pregnancy.

Nursing mothers should not recommence work (particularly the baby is breast-fed) for at least three months after delivery.

Day nurseries must be established if a return to work becomes necessary.

A national scheme should be set up to supervise employment of pregnant women and investigate the possibility of increased financial benefits.

We wish to express our gratitude to Sister W. M. Brown, who did much of the original work in establishing the clinic and making the arrangements with local authorities and the hospitals concerned. We must also express our thanks to the City of London Maternity, St. Mary's Islington (L.C.C.), the Royal Free, the Royal Northern, and other hospitals, and also to the municipal midwives who have co-operated so whole-heartedly in the scheme.

M. H. Shulman (*New Engl. J. Med.*, 1942, 226, 260), impressed with the results in epilepsy of sodium diphenyl hydantoinate, and because of recent work on the psychogenic aspect of bronchial asthma, has tried the drug on six or seven patients suffering from severe asthmatic attacks. The proprietary preparation, dilantin sodium, gave pronounced relief in his small patients aged between 5 and 14 years. He observes that the drug must be given continuously to prevent attacks. In some of these patients the personality was improved.

## FIVE CASES OF JAUNDICE FOLLOWING TRANSFUSION OF WHOLE BLOOD OR HUMAN PLASMA

BY

R. E. STEINER, M.B.

(From an E.M.S. Hospital)

In the last few months 5 cases of jaundice have been observed in this hospital. It was found that these patients had all received transfusions and some time later developed the disease. A similar occurrence has been recorded previously by other writers: Morgan and Williamson (1943) reported 9 cases of jaundice following the administration of human blood products, and Besson (1943) recorded 7 cases of delayed jaundice in subjects who had received blood or plasma transfusions. It seemed, therefore, to be of importance to report the present cases.

Our patients were battle casualties from North Africa, and had been admitted to this hospital from two to three months after having been wounded; they then developed jaundice. All of them had had transfusions of whole blood, human plasma, or both, in varying quantities. The treatment in every case was primarily some form of surgical intervention plus chemotherapeutic measures such as antitetanic and anti-gangrene serum and massive doses of the sulphonamide group of drugs.

#### Case I

Male aged 23; sustained multiple shrapnel wounds of both legs on April 7, 1943. A transfusion of 500 c.cm. of whole blood, followed by 2,500 c.cm. of plasma, was given on the same day. Jaundice was noticed for the first time three months after injury, the patient having had very slight prodromal symptoms of nausea and headache for some days. Thereafter he felt perfectly well. The jaundice deepened considerably during the first three days, was then stationary for one week, and disappeared in the next two weeks.

Physical examination showed slight tenderness on deep pressure over the right subcostal region for a week after the onset of jaundice; the liver and spleen were never palpable, and the temperature and pulse remained normal throughout the illness.

**Laboratory Findings.**—Blood count: Normal during the course of the illness, except for a mononucleosis of 8%. Urine: There was never bile in the urine, but excessive urobilin was present. Faeces: Stercobilin diminished. Van den Bergh: Direct positive reaction; quantitative indirect, 2 mg. per 100 c.cm.

#### Case II

Male aged 28; wounded by a machine-gun bullet in the left thigh on April 11, 1943. A plasma transfusion of 3,000 c.cm. was given on the same day. Three months afterwards he developed loss of appetite and headache, which were followed by jaundice two weeks later. The jaundice deepened steadily over the first week, then became stationary for two weeks; after four weeks only a very faint trace was noticeable. The appetite returned about one week after the onset.

Physical examination after the appearance of jaundice revealed a just palpable liver, which was not tender. The spleen was never palpable. The temperature was slightly raised for the first week of the illness; the pulse remained normal.

**Laboratory Findings.**—Blood count: Normal during the illness. Urine: Slight trace of bile, large amount of urobilin for four weeks. Faeces: Very much diminished stercobilin for 17 days. Van den Bergh: Prompt positive direct after the first week; quantitative indirect, 4.2 mg. per 100 c.cm.

#### Case III

Male aged 21; sustained multiple shrapnel wounds on May 9, 1943. A transfusion of 1,000 c.cm. of whole blood was given on the same day. Jaundice was first noticed three months after the wounding. The patient had no symptoms or

signs up to the second day after the onset, when he developed nausea, anorexia, slight abdominal pain, and vomiting. The jaundice deepened during the first week; it remained stationary for some days, and then began to fade until only a faint trace was observed eight days later.

Physical examination revealed a palpable liver one week after the onset of jaundice, and there was slight tenderness on deep pressure in the right subcostal region. The patient was slightly febrile for the first 10 days of the illness, the pulse rate was slow, and the blood pressure slightly below normal.

**Laboratory Findings.**—Blood count: During the first week normal apart from a mononucleosis of 10% and slight irregularity of red cells. Urine: From the first day of the disease there was excessive urobilin; this gradually diminished, until there was only a trace three weeks after the onset. Faeces: No bile pigments: full of fatty acids for the first week.

#### Case IV

Male aged 36; wounded by shrapnel and machine-gun bullets in the right arm and both legs on March 18, 1943. He received five transfusions between March 21 and April 14—in all, 3,500 c.cm. of whole blood and 250 c.cm. of plasma. Jaundice was first noticed four months after the injury. Two days previously he had had a slight chill and a moderate elevation of temperature, accompanied by generalized aching pains. Then followed a severe illness of two weeks' duration characterized by general malaise, headache, slight abdominal discomfort, anorexia, frequent vomiting, and drowsiness. The jaundice deepened considerably during the first week, then remained unchanged for two weeks, and after another 10 days only a faint trace was recognizable.

Physical examination during the first week of the illness revealed a slightly enlarged liver with moderate tenderness in the right subcostal region. The spleen was never palpable. After the second week the liver was no longer palpable. The pulse was very rapid—120–130 before the onset of the jaundice; it then settled down to 80–100.

**Laboratory Findings.**—Blood count: Normal during the first two weeks of the illness apart from a mononucleosis varying from 3 to 16%; moderate anisocytosis and poikilocytosis. Urine: No bile; excess of urobilin. Faeces: Diminution of stercobilin. Van den Bergh: Prompt direct positive; quantitative indirect, 8 mg. per 100 c.cm.

#### Case V

Male aged 24; received multiple shrapnel wounds in the left leg and chest on March 17, 1943. Transfusion of 500 c.cm. of whole blood was given on March 22. Jaundice was noticed for the first time two months after the wounding. There had been slight abdominal pain and anorexia for two weeks before the onset. He suddenly became very ill on the appearance of the jaundice, which deepened on the second day, and he complained of severe abdominal pain mainly in the subcostal region, incessant vomiting, and headache. At first he was very restless; then gradually he became drowsy and comatose, and died two days after the onset of jaundice.

Physical examination during the last two days of the patient's illness revealed that the liver and spleen were not palpable. The temperature was slightly elevated, the pulse rapid, and the blood pressure normal at first, gradually becoming very low.

**Laboratory Findings.**—Blood count: The blood picture was normal; there was a slight leucocytosis, with toxic granulations of polymorphs. Urine: Faint trace of bile and bilirubin. Faeces: Slightly diminished stercobilin. Van den Bergh: Slightly delayed positive direct; quantitative indirect, 1.8 mg. per 100 c.cm.

**Post-mortem Findings.**—There was generalized jaundice, with haemorrhages into the serous membranes. Other findings of significance were:—Liver: 32 oz. It had a soft yellow mottled surface, and on section showed irregular yellow patches on a dark red background. Microscopical examination revealed complete destruction of liver cells. The only normal-staining elements were the bile ducts, which were loaded with pigment. Some of the liver cells were greatly swollen and pigmented; the others were reduced to a small necrotic mass and were separated from one another. The capsule was wrinkled. Spleen:  $7\frac{1}{2}$  oz.;

moderately enlarged; diffuent and dark red. Histological examination showed the sinuses to be congested. There was widespread blood pigment, both free and in macrophages. Kidneys: Together 12 oz.; flabby; cortex dull, opaque, and swollen, stained dull faint yellow. Microscopically a great degree of swelling of convoluted tubules was seen.

Table showing Details of Cases

Case	Age	Date of Transf.	Amount of Transf. (c.cm.)		Onset of Symptoms	Interval in Days	Date of Recovery
			Blood	Plasma			
I	23	7.4.43	500	2,500	3/7/43	87	26/7/43
II	28	11.4.43	500	3,000	18/7/43	95	16/8/43
III	21	9.5.43	1,000		31/8/43	114	23/9/43 Still faint trace of jaundice 3/8.43
IV	36	21.3.43 23/3/43 24.3.43 29.3.43 14/4/43 22/3.43	500 500 500 1,200 850 500	250	10/7.43	111

#### Discussion

The clinical picture in the five cases described resembled in many ways catarrhal jaundice or infective hepatitis. Generally speaking, it was a slightly febrile illness, with symptoms of nausea, anorexia, slight abdominal discomfort, vomiting, and signs of jaundice, liver enlargement, and tenderness in the right subcostal region. There were, however, some factors which are not usually seen in catarrhal jaundice. In three of the cases there was a definite lack of free bile in the urine, with an excessive amount of urobilin present. In some of the cases—e.g., I, III, IV—there was a marked mononucleosis.

The aetiology of the illness described in these five cases is unknown, and it is impossible, in view of the lack of information about the incidence of jaundice among the untransfused troops in North Africa, to assess the statistical certainty of a connexion between the transfusion and the illness. Nevertheless, the fact that of 245 cases from North Africa, of which approximately 45% had transfusions, 5 developed jaundice while not one of the untransfused cases developed it suggests a connexion between the two. Outbreaks of an illness resembling catarrhal jaundice following inoculation of groups of people with human plasma, serum, or lymph have previously been recorded.

Some aetiological significance must be attributed to (1) the temporal coincidence of the transfusions—within three weeks in four cases—as shown in the accompanying table; and (2) the fact that jaundice has been observed only in our casualties from North Africa and not in those from other theatres of war. It would therefore appear that, while the transfusion may be the cause of the jaundice, certain special circumstances must be attendant on the transfusion before jaundice is produced.

#### Summary

Five cases of jaundice developing two to three months after transfusion have been reported. It is suggested that the transfusion is the cause of the illness. The limited incidence of this complication has been pointed out.

I would like to thank Mr. C. H. Cullen, who is in charge of these cases, and also Drs. J. Doupe and Mary Sharpe, for their help and criticisms.

Morgan, H. V., and Williamson, D. A. J. (1943). *British Medical Journal*, 1, 750.

J. B. Hartzell and W. L. Stone (*Surg. Gynec. Obstet.*, 1942, 75, 1), in an experimental investigation into wound healing, found that this was retarded in guinea-pigs kept on a subcurry diet. In animals operated upon while in a subcurry state, and given high doses of vitamin C, the wounds reached the same degree of tensile strength as in normal animals by the eighth post-operative day. Histological studies showed that the low tenaciousness of wounds in vitamin-C-deficient animals was due to a failure of collagen.

## HISTOLOGICAL EFFECTS OF SULPHONAMIDE-PROFLAVINE MIXTURES IN THE RABBIT

### SOME EXPERIMENTAL OBSERVATIONS

BY

DOROTHY S. RUSSELL, M.D., Sc.D., M.R.C.P.

AND

DIANA J. K. BECK, F.R.C.S.

(Working for the Medical Research Council)

Nuffield Department of Surgery, Oxford

The widespread use of sulphonamide powders in the treatment of wounds has prompted the idea that other substances—notably the acridine antiseptics—might be applied in a similar manner. Thus Mitchell and Buttle (1942, 1943) have claimed beneficial effects from the use of proflavine and disflavine in war wounds. Experiments have shown, however, that acridine powders have a highly destructive effect upon the tissues (Russell and Falconer, 1943; Hawking, 1943). The use of these powders in undiluted form in the treatment of fresh wounds therefore seems undesirable, though they are not of necessity contraindicated for secondarily infected wounds which have failed to respond to other therapeutic measures.

A substantial dilution of proflavine with one of the sulphonamides might be considered a suitable mixture for the prophylactic treatment of wounds, and a blend of one part of proflavine powder in 100 or 200 parts of sulphathiazole has been suggested by McIntosh and Selbie (1943), who find that proflavine is more potent than the sulphonamides in infections with some of the gas-gangrene organisms. Sulphathiazole powder has been found by Glynn (1942) to have a negligible damaging effect upon the tissues in experimental wounds, and in this respect is preferable to either sulph-anilamide or sulphapyridine.

The present experiments demonstrate in rabbits the effects of proflavine-sulphonamide mixtures upon (a) muscle and subcutaneous tissues, and (b) the brain.

#### Muscle and Subcutaneous Tissues

In this group the powder tested was composed of 1 part of proflavine sulphate and 99 parts of sulphathiazole. The experiments were similar to those described by Glynn. Under ether anaesthesia an incision 1 to 2 cm. long was made in the depilated skin of the thigh, and a pocket (about 2.5 cm. diameter), made between the panniculus carnosus and the skeletal muscle by introducing and opening the blades of blunt scissors, was filled with about 0.25 g. of the powder. The wound was then closed. The disk of blood-clot also inserted Glynn was omitted. Six rabbits were treated in this way.

phathiazole alone being introduced into the left leg, and a mixed powder into the right. The animals were killed after 1, 2, 4, 8, 10, and 16 days respectively.

#### MACROSCOPICAL CHANGES

The site of operation in general appeared swollen and felt boggy for the first few days after operation. In four of the animals the right side was considerably more swollen than the left, and in one of these slight oozing of clear yellowish fluid was observed on the third day at the point where a stitch had been lost. From the fourth day onwards this wound was dry and the inflammation subsided. In the remaining two animals the left leg showed the greater swelling. All wounds appeared to heal in a normal manner with the single exception mentioned.

When the block of tissue including the operation area had been excised, fixed in formaldehyde, and sliced, the powder was identified as a lenticular, cheesy mass about 2 cm. in diameter and 0.3 or 0.4 cm. thick, which decreased with time and was reduced to a linear streak by the eighth day. With pure sulphathiazole the changes in the surrounding tissues were limited to slight oedema on the first day, with traces of haemorrhage in the adjacent fasciae and deep aspect of the skin. With the mixed powder there was on the first day severe oedema with diffuse haemolytic staining of the deep aspect of the skin, extending from the site of operation to the base of the tail and involving the fascia covering the skeletal muscle for a distance of 1 cm. from the pocket. On subsequent days the staining of the fascia was replaced by petechial haemorrhages, which similarly extended for distances up to 4 cm. from the site of opera-

tion. There was a zone of discoloration up to 2 mm. deep in the skeletal muscle, varying from yellow on the first day to brownish pink or yellowish grey in later stages. Oedema of the adjacent tissues, and particularly of the skin, persisted up to the sixteenth day over the pocket, which was replaced after the eighth day by a lenticular mass of gelatinous greyish-yellow material.

#### MICROSCOPICAL CHANGES

1. *With sulphathiazole alone* oedema of the dermis, panniculus carnosus, and the deep fascia was conspicuous at first, but had almost disappeared by the fourth day. Most of the powder had been absorbed by the fourth day, but a few crystals were found on the tenth. The site of the powder beneath the panniculus carnosus was identified by a capsule of closely felted filaments of fibrin, which became increasingly folded as the space collapsed. By the fourth day this capsule was sparsely infiltrated by polymorphonuclear leucocytes and large mononuclear cells, and immediately about it lay a thin zone of proliferating fibroblasts. By the eighth day the capsule was broken at many points by the ingrowth of granulation tissue, which lined most of the enclosed space (Fig. 1). The

FIG. 1.—Border of skeletal muscle and lateral angle of pocket 8 days after insertion of sulphathiazole powder. The borders of the pocket are replaced by granulation tissue. H. and E.  $\times 21$ .

appearances were similar on the tenth day, but by the sixteenth day all traces of the cavity had been obliterated by collagenous tissue. The panniculus carnosus immediately over the pocket was involved by the formation of granulation tissue, but the muscle fibres, though separated, did not undergo degeneration or necrosis. The subjacent skeletal muscle of the thigh showed slight oedema in early stages but underwent no degeneration in any instance.

2. *With sulphathiazole-proflavine mixture* the histological changes differed from those which followed the introduction of sulphathiazole alone, first, in the persistence of local oedema up to the sixteenth day; secondly, in the conspicuous development of haemorrhagic necrosis in the dermis, the panniculus carnosus, the subjacent skeletal muscle and its fascia (Fig. 2); and, thirdly, in the consequent retardation of healing in these layers although the skin incision healed as rapidly as in the controls. Thus the panniculus carnosus was completely necrotic throughout the length of the section (2.5 cm.) in the animal killed after one day, and the necrosis extended laterally for a similar distance in the subjacent fascia, which was greatly swollen. Yet the zone of necrosis in the skeletal muscle was no deeper than about 1 mm., and in two of the animals was limited to the most superficial fibres. The extent of necrosis about the pocket of powder resulted in a retardation of healing. Thus granulation tissue did not appear until the eighth day; it then occupied the deep border of the subjacent necrosed skeletal muscle and the surface of the deep fascia over it lateral to the pocket, while tongues of young fibroblasts penetrated through the subcutaneous tissue to within 2 mm. of the fibrin capsule about the pocket. Even by the sixteenth day the fibrin capsule persisted at many points, especially along the superficial border towards the dermis.

## COMMENT

The histological effects of sulphathiazole powder alone are thus negligible, confirming the observations already made by Glynn. A mixture of proflavine sulphate and sulphathiazole (1:100) is substantially damaging to muscle and connective tissue: necrosis and haemorrhage are widely distributed along fascial planes and in loose connective tissue, but the penetration of solid masses of muscle appears very limited.

Since these observations were made some parallel experiments on rats have been reported by Selbie and McIntosh (1943). They inserted about 10 mg. of similar powders beneath the panniculus carnosus of the abdominal wall on either side of the mid-line. The area exposed to the powders was of similar dimensions to that in our experiments. The histological results in these rats appear to have resembled those obtained by us in the rabbit except in two particulars. First, the

FIG. 2.—Same animal as in Fig. 1, showing necrosis of skeletal muscle and fascia over it 8 days after insertion of proflavine-sulphathiazole mixture. H. and E.  $\times 21$ .

panniculus carnosus in the rat underwent the same degree of necrosis following exposure to both kinds of powder. Secondly, no retardation of healing was observed in the rat in comparison with the areas treated by sulphathiazole alone, in spite of the apparently greater damage inflicted by the proflavine mixture. To some extent these divergences might be attributable to the use of different animals and different sites. But more important, probably, is the difference in the severity of the test. Thus in the experiments of Selbie and McIntosh a much smaller quantity of the powder was dispersed in a thin film between the muscle layers, while we, following Glynn, inserted enough powder to form a lenticular mass several millimetres thick. The observed difference in the two series is a warning against the use of excess of the proflavine-sulphathiazole mixture.

## Central Nervous System

Sulphapyridine was substituted for sulphathiazole in these experiments on account of the known epileptogenic effects of the latter. In a few animals sulphadiazine was used. Craniotomy was performed on 28 rabbits, the technique being the same as in earlier experiments (Russell and Falconer, 1943). Details are given in the Table.

The animals were killed at either 2 or 4 days after the operation. During this period weakness of the right limbs and excitability were noticed in both animals in Group 1, and to a less marked extent in a variable number of animals in all the other groups.

*Pathological examination* showed a lack of uniformity in the reaction of the meninges and brain in the exposed area. In Groups 1 to 3 inclusive a proportion of the animals, as shown in the Table, exhibited a haemorrhagic necrosis that

Group	Mixture Used	No. of Animals	Severe Reaction
1	Proflavine sulphate - sulphapyridine, 1:25	2	1
2	" " " " " 1:50	7	3
3	" " " " " 1:100	9	3
4	" " " " " 1:200	7	0
5	" " " " " sulphadiazine, 1:200	3	1

extended down to the wall of the lateral ventricle. In the rest the reaction was limited to focal meningeal haemorrhage and oedema of the cortex, accompanied by severe degeneration, with or without necrosis, of a superficial zone not exceeding 1 mm in depth. In Group 4 this zone did not exceed 0.5 mm. In depth, and the reactions in this group were thus of a more consistent character though somewhat variable.

No satisfactory explanation of these uneven results can be offered. Examination of the powder under low powers of the microscope suggested that uneven distribution of the proflavine particles might be responsible, but regrounding the mixture in an agate mortar, and trials of specially prepared samples kindly provided by Messrs. May and Baker Ltd., made no obvious difference to the results. Nor did accidental trauma to the brain during the operation appear to be a factor. Thus superficial trauma, due to a bleeding vessel or to a small abrasion, was noted in five of the animals. In two of these the ultimate damage to the brain was found to be severe: in the other three it was slight. Small variations in the amount of powder used might be regarded as a possible cause, but in one of the animals in Group 3 an excess of powder was deliberately applied, and in this animal the damage was limited to marginal oedema, haemorrhage, and necrosis, together less than 1 mm. deep. We are thus left with the unsatisfactory suggestion that variations in the results are due to factors inherent in the individual. It is nevertheless clear, as indicated in the Table, that the incidence of a severe reaction falls with a diminishing proportion of the proflavine used in the mixture.

## Conclusions

The first group of experiments here reported confirms previous observations that the insertion of substantial amounts of sulphathiazole powder into clean incised wounds is harmless to the tissues. Similar amounts of a powder consisting of 1 part of proflavine sulphate to 100 parts of sulphathiazole caused considerable damage to the neighbouring muscle and connective tissues, though the penetration of the proflavine into solid masses of muscle appeared to be slight and rather uneven.

The experiments on the rabbit's brain with mixtures of proflavine and sulphapyridine powders indicate a similar damaging effect of the proflavine, though the results in this group are not so clear-cut. Mixtures containing only 0.5% of proflavine sulphate are appreciably less damaging than those with higher percentages of this compound. Comparison with earlier experiments shows that both proflavine solutions (1:1000) and sulphonamide powders are preferable from the standpoint of histological effect.

It is a pleasure to thank Prof. J. A. Gunn for providing accommodation for the animals. Our expenses were defrayed by a special grant from the Medical Research Council, and the work was carried out on behalf of the Council's War Wounds Committee.

The National Institute for the Blind in its 74th annual report records a year of remarkable activity among the hundreds of sightless physiotherapists trained at the Institute's School of Massage and now engaged in the work professionally. At the clinics attached to the London headquarters there have never been so many patients in attendance or so many treatments given. The numbers at the evening clinic were respectively 7,610 and 14,117 as compared with 5,185 and 9,859 in the previous year; and at the Eichholz Clinic, which is now recognized as a fracture clinic by the Ministry of Health, they were 4,800 and 11,616, as against 2,972 and 7,657.

## VACCINATION AGAINST TYPHUS FEVER

BY

JOHN B. PENFOLD, M.B., B.S.

*Emergency Pathological Service Laboratory, St. Andrew's Hospital, Billericay, Essex*

The incidence of agglutinins for *Proteus* OX 19, OX 2, and OXK in the British population has rarely been investigated. It was reported in the Monthly Bulletin of the Emergency Public Health Laboratory Service (Aug., 1942, p. 6) that in 100 "normal" sera no agglutination was obtained with any of the three suspensions above 1/128 dilution. The titres for OXK were approximately double those found for OX 19 and OX 2, and it was suggested that titres of 1/80 or over with OX 19 are unlikely "in the absence of exposure, either recent or remote, to typhus infection." Approximately nine-tenths of these sera showed a titre of 1/16 or less with the OX 19 and OX 2 suspensions.

There is only one report from this country on vaccination against typhus fever and its effects on the Weil-Felix reaction. Felix (1942), in a report to the Medical Research Council, gave briefly the alterations in the OX 19 agglutinin titre evoked by various vaccines. Considering 100% or greater increase in agglutinin titre as significant, very variable results were found with both the type and the batch of vaccine used. With vaccines of the Cox type the proportion showing a significant rise in titre varied with the batch of vaccine from approximately 5 to 50%.

## The Present Investigation

In the investigation now reported a vaccine prepared by the Connaught Laboratories, Toronto, from a European louse-borne strain of *Rickettsia prowazeki* grown in the yolk-sac of chick embryos (Cox, 1938) was used. It was issued on Nov. 4, 1941, and with a batch of vaccine of the same date Felix obtained a significant increase in OX 19 agglutinin titre in about half of those inoculated. Twenty-three public health workers were vaccinated and their Weil-Felix and clinical reactions were investigated. At weekly intervals each received 0.25 c.c.m., 0.5 c.c.m., and 1 c.c.m. of vaccine subcutaneously, and three months later a fourth dose of 1 c.c.m. Samples of blood were obtained on four occasions: (1) before the first injection; (2) a fortnight after the third injection; (3) before and (4) a fortnight after revaccination; these were tested for OX 19, OX 2, and OXK agglutinins. The method used in the Weil-Felix test was as follows:

Concentrated suspensions of OX 19, OX 2, and OXK, prepared at the Standards (M.R.C.) Laboratory, Oxford, were diluted 15 times and added in equal quantity to serial serum dilutions, the final dilutions of serum being 1/5, 1/10, 1/20, 1/40, 1/80, 1/160, 1/320, and 1/640, while that of the suspension was 1/30. All tubes were incubated at 56° C. for 4 hours, and the test was read after standing at room temperature overnight; the last tube showing standard agglutination was taken as the titre.

Before vaccination the titres for OX 19 and OX 2 in the cases were all 1/20 or less, the majority showing no titration at 1/5. With OXK, 20 out of the 23 showed titres ranging from 1/20 to 1/160, the commonest being 1/40. No higher titre was observed.

## Relation of Agglutinin Titres at Various Stages to the Number of Cases

Suspensions	Titre	Before Vaccination	Number of Cases		
			2 Weeks After Vaccination	3 Months After Vaccination	2 Weeks After Revaccination
OX 19	0 to 1/10	20	10	15	4
	1/20 to 1/160	3	13	8	19
OX 2	0 to 1/10	22	13	21	11
	1/20 to 1/80	1	10	2	12
OXK	0 to 1/40	15	1	21	18
	1/80 to 1/640	8	22	2	5

Vaccination in the majority of cases resulted in an increase in titre of the three agglutinins. Three months later they had decreased, but not to the pre-inoculation level. After revaccination the OX 19 and OX 2 agglutinin titres rose again, the

former above and the latter to the level recorded after primary vaccination, while the OXK titres were not appreciably altered. These results are tabulated below by correlating the number of cases with the agglutinin titres of their sera.

Even after revaccination the highest OX 19 agglutinin titre was 1/160 (1 case), and OX 2 was 1/80. If more than 100% increase in OX 19 agglutinin titre is taken as significant, 14 cases out of 23 (61%) showed it after primary vaccination and 17 (74%) after revaccination.

Reactions to the injections were as a rule quite slight, and diminished in severity with each additional injection. General reactions, such as occasional malaise, headache, drowsiness, and muscular pains, were less frequent than local reactions, which presented as areas of erythema, swelling, and stiffness, usually starting 12 to 24 hours after the injections and lasting a day or two.

## Summary

Twenty-three people were vaccinated with a Cox vaccine against typhus fever and revaccinated three months later.

The Weil-Felix reactions on these individuals showed low normal agglutinin titres, which were increased after vaccination, and, in the case of OX 19, after revaccination.

The reactions to the vaccine were slight.

I wish to thank the Medical Research Council for the supply of vaccine and Prof. S. P. Bedson for his helpful advice.

## TREATMENT OF PEDICULOSIS CAPITIS

BY

ERIC BLACKSTOCK, M.D., B.Sc., D.P.H.

*Venerable Diseases Officer, Birkenhead County Borough*

Coincident infestation of the skin by *Sarcoptes scabiei* and of the scalp by *Pediculus humanus capitis* has become more common among patients attending the scabies clinic in Birkenhead. From the table given below one can see the steep rise in lousiness recorded in school-children during routine cleanliness inspection; it also gives a fair indication of the increase in lousiness of many families in the borough. It is not an uncommon sight to find children's scalps in an unbelievably filthy condition, with lice present in thousands.

## Results of Cleanliness Inspections carried out by the Health Nurses in the Elementary Schools, 1938-43

Year	No. on School Rolls	No. with Nits	No. with Vermin	Total No. Unclean
1938 .. ..	20,101	2,499	253	2,808 (13.9%)
1939 .. ..	19,519	2,781	89	2,959 (15.16%)
1940 .. ..	14,989	1,857	146	2,086 (13.92%)
1941 .. ..	11,753	1,863	107	2,141 (18.22%)
1942 .. ..	14,398	2,412	115	2,871 (19.94%)
1943 (Jan.-June 30)	14,999	2,420	388	3,026 (20.17%)

These figures refer to the number on the rolls of the elementary schools at the end of the December term of each year, except in the case of 1939, the figures for which refer to the number on the rolls at the end of the summer term; all schools were closed in the following September owing to the outbreak of war.

Since the publication by J. R. Busvine and P. A. Buxton (*B.M.J.*, 1942, 1, 464) of their use of lethane oil as a means of controlling head lice, I have employed it at the scabies clinic with excellent results so far as the killing of lice is concerned, but it leaves much to be desired regarding its effect on nits cemented to the hair. It is unfortunate that scabies seldom if ever, affects the scalp, except perhaps at the nape of the neck, otherwise it would not have been left to me to draw attention to the clinical finding that an emulsion of benzy benzoate is the treatment *par excellence* for pediculosis capitis even when complicated by impetigo, etc. Its solvent action on the cement of the nit and its lethal action on the louse make it a very quick and effective remedy in "delousing."

One must emphasize that it is necessary to use a non-irritating formula of benzyl benzoate emulsion, as the majority

of the emulsions tried first at the clinic were too painful for the patient. However, the latest formula of ascabiol can safely be used twice daily for three or four days, though I have seldom found it necessary to treat for more than three days. This is a most important matter, as unsuitable emulsifying agents in the benzyl benzoate preparation will soon cause sore scalps and poor results. The action on the nit is a "combined operation," because, used alone, neither benzyl benzoate nor the emulsifying agent gives the desired result nor does their use as separate solutions applied one after the other on the same or different days.

#### Method

All the experiments carried out were designed to remove the nits from the hair without the usual tedious work of combing. At first hairs were removed and put into sealed tubes to act as a control for the viability of the nit. This practice was discontinued when it was realized that the object of the experiment was not to determine whether the nit was dead or alive but to discover an easy method of freeing the scalp from nits about whose viability one could never be sure. The results were briefly as follows, after applying the four undermentioned solutions:

Solutions used	Effect on Nits attached to Hairs 24 Hours Later
1. 25% benzyl benzoate dissolved in industrial spirit	Nits still remain adherent to hairs
2. Emulsifying agent (trichloroamine stearate)	No apparent effect on nits
3. Ascabiol (new formula)	Nits loosened, removed by simple wash with soap and water
4. Lethane oil	Nits appear more strongly attached to hairs than before

The effect of ascabiol emulsion is superior to that of lethane oil, as the lice appear to be dissolved in the solution.

The severe cases of infestation with *Pediculus capitis* in which coecal infection had occurred with much crusting of scalp and enlargement of the post-cervical glands were treated daily with the ascabiol. Most of the scalps were clean and healed in less than a week. I do not know of any other form of treatment which gives such quick results, despite the trial in hospital of numerous preparations over a period of many years, with both in-patients and out-patients.

For those wishing to carry out this method of treatment—which is now my routine for all scalps infested with (1) nits only, (2) lice and nits, (3) lice, nits, impetigo, etc.—I have given the technique used at the scabies clinic, where these experiments were carried out by myself and the nursing staff. This method has relieved the staff from the tedium of fine combing: simple washing with soap and water was sufficient to remove all remaining nits.

#### Routine Treatment now used

First day: Head coated with ascabiol (new formula); application made with painter's brush  $1\frac{1}{2}$  in. or 2 in. wide.

Second day: Hair washed with soap and water.

One week later: Head inspected carefully for possible reinfection.

If the infestation is a very heavy one this treatment is given twice in 24 hours. If there is coincident coecal infection of the scalp the treatment is repeated on the second and third successive days; then one of the common forms of healing ointment is given until the inspection of the scalp one week later. Ointments in use are mostly preparations of sulphonamides in Mumford's base, lanette wax, or vaseline. In cases of seborrhoea, sulphur and salicylate in vaseline are sufficient. As already mentioned, treatment with ointments is seldom necessary.

I wish to thank the medical officer of health, Dr. D. Morley Mathieson, for permission to carry out this work at the scabies clinic; also the nursing staff, whose assistance made the work possible. Messrs. May and Baker kindly supplied the benzyl benzoate emulsion "ascabiol" (new formula) used in these experiments.

L. E. McCrea (*J. Urol.*, 1942, 47, 818), who records an illustrative case, states that congenital absence of the penis is one of the rarest anomalies on record, only ten previous cases having been reported. It must not be confused with pseudo-hermaphroditism, hidden penis, or epispadias. The present case was that of an otherwise normal young man who wished to marry. During sexual excitement the presence of erectile tissue in a small eminence on the perineum was manifested by some enlargement, and on manipulation an apparent ejaculation of semen took place.

## Medical Memoranda

### Recovery from Actinomycosis of the Liver

I can find no other report of recovery from actinomycosis of the liver, and therefore consider that this case should be put on record.

In Oct., 1928, a hitherto healthy young man began to complain of abdominal discomfort and anorexia. He wasted very rapidly and by the end of the year was extremely ill. His conjunctivae turned yellow, and on examination a large epigastric mass was discovered. In Feb., 1929, he was operated on at Swansea and a portion of the tumour was removed for microscopical examination. After the operation the surgeon informed the patient's wife that there was a "tumour of the liver" as big as my two fists; that he thought it was malignant; and that he was afraid her husband had but a short time to live. Two months later the tumour had completely disappeared and the patient seemed perfectly well. Now, 15 years later, at the age of 46, he has just been passed for insurance purposes as a first-class life.

The report on the section was "actinomycosis of the liver." Because of an article of mine which was published in the *BMJ* of Feb. 23, 1939 (p. 347), the patient was treated with 5-minim doses of triiodine iodide 3 times a day in milk, and in April of that year he was sent by Dr. Taylor of Swansea to see me for my opinion as to whether the treatment should be continued longer. As a precautionary measure I advised him to take one dose daily for a further 6 weeks.

Bristol.

HUBERT CHITTY M.S., F.R.C.S.

### A Case of Congenital Microcolon

Cases of microcolon in the literature stress the extreme rarity of the condition. Theremin (1877) recorded two cases in 111,451 necropsies in Vienna. Greig (1925) reviewed the literature of the condition and published three cases in which the entire colon was diminutive, and in which there were, in addition, abnormalities in the small gut. The case here recorded is one in which only part of the colon was affected, and is comparable to two cases reported by Klippel and Feil (1912) and Lesné and Baruk (1923).

#### CASE HISTORY

The patient was a male first-born infant of 5½ months. Both parents were young and healthy. At the age of 6 weeks the child had a mild skin eruption, which was followed by an attack of acute gastro-enteritis; these responded to treatment. A month later the patient developed acute bronchitis and enteritis, and again recovered. The final illness began with a recurrence of the bronchitis, which progressed to bronchopneumonia with a left-sided empyema. During this last illness the abdomen showed gradual and progressive dis-

Photograph showing transverse colon rolled downwards to reveal the transition in size taking place proximal to the splenic flexure. S, Stomach, with omentum removed. C, Transverse colon. M, Microcolon.

tension, which was associated with severe constipation. Repeated enemata produced small results in which the faeces were normal in appearance. Rectal examination disclosed no abnormality. A straight radiograph of the abdomen showed gas distension of the small intestine and the caecum.

#### POST-MORTEM EXAMINATION

A left-sided empyema was present in association with a small superficial lung abscess; this condition was regarded as the cause of death. The condition of the bowel was of particular interest. The gut was normal in position and fixation. The small intestine was distended, and the distension was more pronounced as the gut was traced distally. The large intestine was distended up to a point

about 1½ inches proximal to the splenic flexure, where the size of the colon became diminutive. The entire descending and pelvic colons were very small. The lumen of the affected segment of gut was quite patent, but was reduced in diameter. There was no evidence of any form of organic obstruction at the junction of the normal colon and microcolon or elsewhere.

It is a feature of particular interest that the segment of colon involved was that deriving its blood supply from the inferior mesenteric artery and corresponding embryologically to the hind-gut.

## Traumatic Rupture of the Superior Vena Cava

The following case is considered unusual enough to justify description of the post-mortem findings in some detail. It is that of a West African soldier, of limited horsemanship, who was riding his officer's polo-pony at a gallop when the pony swerved to one side and the rider struck his chin against a metal pylon. The force threw him from the pony. The man was seen to give a few gasps, and died within two minutes.

## FINDINGS AT NECROPSY

**External Appearances.**—The body of a well-developed African male about 25 years of age, with the head lolling abnormally. Severe bruising and abrasions were seen on the forehead, chin, and left hip, and a few scratches on the front of the left thigh. The nose was battered in, and the mouth contained much road-grit. There was no haemorrhage from either auditory meatus.

**Internal Appearances.**—**Skeletal system:**—The cervical spine had fracture-dislocations of C3 and C5, the fractures involving the articular pillars with posterior displacement of the neural arch. The bodies of the vertebrae were intact. **Heart and Mediastinum:**—The pericardium was under tension due to contained blood, and several large bubbles of air were found. About half a pint of liquid blood was present in the pericardial sac. The heart was covered with a slight excess of pericardial fat, and the right ventricle was considerably dilated but empty. There were a few small subendocardial haemorrhages in the left ventricle. All four valves were normal. The coronary arteries were free from atheroma, but small bubbles were visible within their lumina and could be expressed, especially from the anterior descending branch of the left coronary artery. The aorta was normal. The superior vena cava was completely ruptured across just within the pericardial sac, about three-quarters of an inch from its entry into the right auricle. The distal end of the vein was separated from the proximal end by some two inches, the intervening space being filled with blood-clot. The escaped blood had extravasated around the base of the aorta, downwards behind the heart, and upwards as far as the thyroid, to form an irregularly trilobate mass (see Fig.).

Figure showing extent of extravasation. The interrupted shading represents clot behind the haemopericardium.

**Lungs:**—The right pleural cavity was partially obliterated by old dense fibrous adhesions. The left pleural cavity was normal, but an irregular-shaped haemorrhage, about 1 in. by 2 in., was present under the parietal pleura underlying the fourth and fifth ribs in the mid-axillary line. There was no fracture of the ribs in this region or elsewhere. The visceral pleurae were both intact. At the antero-superior margin of the left lung a large emphysematous bulla was present, filled with blood and air. Many small bubbles were visible under the pleura on both the mediastinal and the costal surfaces. The lungs were bulky, firm, dark, and erepitate. The lower part of the trachea and the main bronchi were filled with frothy blood. On cutting across the lungs they were seen to be turgid with contained blood.

The only other finding of note was that the left ureter was thickened and congested, and there was a cylindrical swelling 1 in. long situated about 3 in. from the kidney pelvis. This was due to schistosomiasis, a condition not uncommon in the West African. The bladder was normal.

## COMMENT

From the injuries to the nose, forehead, and chin, the grit in the mouth, and the double fracture-dislocation of the cervical spine, it is thought likely that a severe degree of hyper-extension of the latter occurred. Presumably this caused considerable tension on the superior mediastinal contents, resulting in rupture of the superior vena cava. Death could not have been instantaneous, as evidenced by the subendocardial haemorrhage, the air bubbles in the coronary arteries, and the blood-distended lungs showing interstitial emphysema.

I am indebted to Brig. R. A. Hepple, D.D.M.S., West African Forces, for permission to publish this case.

## Reviews

### SKIN GRAFTING OF BURNS

*Skin Grafting of Burns.* By J. Barrett Brown, M.D., senior consultant in plastic surgery, E.T.O., U.S. Army; associate professor in surgery, Washington University; and Frank McDowell, M.D., assistant in clinical surgery, Washington University. (Pp. 204; illustrated, 30s.) London: J. B. Lippincott Company.

This is an excellent concise statement of the value of skin grafting in the treatment of burns. The authors have drawn from their experience during many years, to which are added observations by one of them (Dr. Barrett Brown) in this country since the war started.

The book is essentially practical, and therefore no attempt is made to sift or discuss the great mass of theoretical and controversial matter that has filled the medical press in recent years. The authors describe the methods they have found most useful and the reasons for their choice. Early treatment comprises adequate cleansing, open surgical drainage (including baths), and pressure dressings. The disadvantages and danger of coagulants are discussed. Careful histological studies of healing burns, of unhealed ulcers of donor sites, and of healed grafts are included to explain epithelial repair. Split-skin grafts applied early are recommended in all deep burns to obtain primary healing. The exact technique is described, and photographs of grafts as much as 36 in. long are reproduced. The many methods used in late repair are next described. The authors appear to have had most success with split-skin grafts and many excellent results are illustrated. Flaps and tubed pedicles are also used, but these are not described in great detail. There is an interesting chapter on the use and limitations of homografts, and another on the faults of grafts.

This is a book that all should read, if only to learn from the many excellent illustrations the best methods for quick restoration of function in these so often tragic cases.

### THE TOO-PROTECTIVE MOTHER

*Maternal Overprotection.* By David M. Levy, M.D. (Pp. 417, \$4.50 or 30s.) New York: Columbia University Press; London: Oxford University Press, 1943.

This book is the product of collaboration by the staff and students at the Institute of Child Guidance of New York. The importance of mother-child relationship in the study of psychiatry is pointed out, and the "broad front" approach of child guidance team-work is contrasted with the "narrow front" approach of psycho-analysis. Both may be useful. From the large volume of child guidance material a number of cases of "obvious" over-protection were selected, and these could be contrasted with other groups investigated by different groups of workers. Five groups of over-protection could be differentiated, but only the first can be considered as "pure." They are: (i) over-protection of a wanted child; (ii) predominance of but inconsistency of over-protection which is mixed with rejection; (iii) over-protection in infancy followed by rejection on the arrival of a second child; (iv) mild maternal over-protection; (v) non-maternal over-protection.

The criteria of maternal over-protection are taken as (a) excessive contact; (b) prolongation of infantile care; (c) prevention of independent behaviour; (d) maternal control. This last criterion may be modified when the mother is "conquered" by the child and becomes submissive to it at home while maintaining her protective attitude towards it in face of the outside world. Excessive contact is characteristic especially in relation to boys sleeping with their mothers, but incestuous fantasies or activities were not found to be prevalent. Prolongation of infantile care is examined statistically in relation to breast-feeding, which is shown to be prolonged in over-protected children. Prevention of independent behaviour is dealt with in relation to school performance. The over-protected child tends to show superior educational achievement, relatively high scores in language, poor score in arithmetic (because mothers are not good at arithmetic and because the child is not sent on messages which need arithmetical calculations?), and special interest in reading with a general lack of interest in sports. Other effects of this kind of over-protection are discouragement from forming friendships.

and playing with other children, and the reputation of being "sissy" outside the home, although such a child may be very tyrannical in the home.

It was found that many too-protective mothers were over-anxious for children because of long periods of sterility and the like. There is no conclusive evidence that this over-apprehensiveness was compensatory for an unconscious hostility to pregnancy. Sexual maladjustment with the husband was common, as was the factor that the couple had little in common in their social life. Many of the over-protecting mothers had been themselves deprived of satisfactory parental relationships. The mothers who were the subject of this study tended to be aggressive and their husbands to be submissive. There was a distinct tendency in the family histories for grandparental interference.

The behaviour of over-protected children is characterized by disobedience, impudence, tantrums, excessive demands, and varying degrees of tyrannical behaviour. At school they behaved fairly well—perhaps because they were intelligent and their mothers ambitious. In the case of three boys who were troublesome in school both mother and child were of poor intelligence. These children found difficulties in making friends, though camps made this better. No particular sexual disturbances were found. They suffered from feeding difficulties, not from sleep or secretory troubles. They were well developed physically, and in general well looked after.

Methods of treatment, in addition to remedying physical defect, consisted in psychotherapy of the mother, to get her to realize what she was doing and release the child; of the father, to persuade him to take more interest in and exert more authority over the child; of the child, to show him why he was dependent and tyrannical and to induce him to take a more responsible attitude to life. Environmental therapy consisted in attempts to widen the interests of the mother and to bring her into closer social relationship with her husband, so that the parents could be husband and wife as well as father and mother. The child was provided at least with opportunities for contacts and activities outside the home. The social worker attempted to give practical demonstrations in the home of how the situation should be handled. The main thing was to separate mother and child by some means or other, if necessary by periods of absence from each other. On the whole, treatment showed satisfactory results, but as a rule was difficult and took up much time. A final chapter is devoted to a description of case studies and follow-up; and, in an appendix, detailed summaries are given of twenty cases.

This book is a masterly exposition of a collective research into a limited but important field of personality relationship, which has no small influence on the development of the adult personality, and it can be recommended to all who are attracted by child psychiatry as an interesting study and a valuable book of reference.

### NARCO-ANALYSIS

*Narco-Analysis. A New Technique in Short-cut Psychotherapy. A Comparison with Other Methods; and Notes on the Barbiturates.* By J. Stephen Horsley. Oxford Medical Publications. (Pp 134. 8s. 6d.) London: Oxford University Press, 1943.

This small book covers the various aspects of the treatment of psychiatric conditions by means of the injection of an atrovane barbiturate to produce a degree of narcosis in which the patient is more communicative than in ordinary circumstances. The technique and its various applications are described.

The special interest of the book lies in its description of the few cases of the melancholic or, more rarely, of the schizophrenic type in which the method has enabled psychotherapy to be applied successfully, though unfortunately the case records are hardly full enough to be satisfactory. Incidentally the claim is implied by the author that he was the first person to use this method in this country. This, indeed, is probably true so far as any "analysis" is concerned, but he was not in a position to know that the first person to use it as a method of treatment in psychogenic disorders in this country was Dr. Broome of Oldham, who employed it with success in hospital practice as a means of conveying therapeutic suggestions in a wide variety of psychiatric conditions.

Dr. Broome has, however, forborne to publish his results from an excess of modesty.

This book is a convenient if enthusiastic summary of the field of application of the method, and it is to be hoped that those who have not tried it out may be stimulated to use it in the carefully selected field where it is useful chiefly as a time-saving device. When the exigencies of wartime make it a tempting short-cut, it can easily be abused.

### Notes on Books

In these days of crowded life, when the fashion is to concentrate everything from vitamins to air assaults, there may be a growing band of embryo surgeons who relish the idea of concentrated textbooks. The day may come when the operator has before him in the theatre a sterile guide to surgical technique even as the conductor has his score of music. The majority still believe that operative surgery is an art which cannot be so practised, neither can it be learned from summaries pinned to the bedroom wall. For those to whom the concise presentation of facts in tabulated form does appeal Dr. MORRIS A. GOLDBERGER's little book *Gynecologic Surgery* will have a special fascination. It contains an amazing amount of information in its 154 pages of summarized text. It is entirely devoid of diagrams, but every third leaf is left blank for the convenience of the reader who wishes to add his own notes or sketches. The subject is covered in 14 sections, which for the most part are arranged on an anatomical basis. An adequate index concludes the little book, which is published in this country at 12s. 6d. by the Oxford University Press.

Dr. J. NEWTON KUGELMASS has written *Clinical Pediatrics* as a member of the outline series published at 12s. 6d. by the Oxford University Press. It is entirely in the form of a synopsis, with headings and subheadings to facilitate easy consultation. As a work of reference it will enable the reader to get a quick view of symptoms and treatment, but it builds up no clinical picture and it gives little indication of the relative importance of different subjects. The seventeen sections range from "growth and development" to "infectious diseases." "Blood disorders" are described in 62 pages and "respiratory disorders" in 15. This gives some indication of the lack of balance, possibly due to the method of classification used, for both asthma and tuberculosis appear outside the respiratory section. In view of the nature of the book the index might have been more extensive. There are no illustrations.

*An Introduction to Group Therapy.* by S. R. SLAVSON, printed in New York under the auspices of the Commonwealth Fund, is published here by the Oxford University Press at 11s. 6d. There are two justifications for group therapy—first as a time-saving device, and secondly because many psychiatric disorders are concerned with failure to adapt to the demands of society so that treatment in the company of others under controlled conditions may have special possibilities of its own. This book, which is systematically written and well documented, describes the indications for group therapy and its technique, and discusses the interpretation of what actually happens in the therapeutic process. Those who are themselves concerned with the treatment of children will be particularly interested in the opinions of the author as to the types of character and personality suitable for group therapy. A merit of the work, which can be warmly recommended to workers in child guidance in this country, is that it is based on much observation and is not biased by theoretical preconceptions. The group therapy of adults is given only a page or two in connexion with the treatment of mothers, originally in relation to their children's problems.

The Department of Scientific and Industrial Research has issued through H.M. Stationery Office at 4s. 6d. No. 3 of volume 14 (Dec., 1942) of the *Index to the Literature of Food Investigation* compiled by Agnes Elisabeth Glennie, B.Sc., and Catherine Alexander, B.Sc. These brief abstracts are, as usual, listed in sections, followed by an index of authors. The items in the present number run from 933 to 1455 inclusive.

A second edition of *The Nupercaine Handbook*, originally known as *The Percaine Handbook*, has been published by Messrs. Ciba. They are to be congratulated on having collected a voluminous literature on the use of nupercaine and reduced it to a concise but very readable form. The publication is in two parts, the first dealing with spinal and the second with local anaesthesia. Both surgeons and anaesthetists will find much of interest in these booklets, while those who use nupercaine will find them invaluable. A very complete list of references is given at the end of each part. Copies may be had on request from Ciba Limited, Horsham, Sussex.

*Correction.*—The reviewer of *Blood Grouping Technic*, by Schiff and Boyd (Jan. 1, p. 13), wishes to correct a small slip in his notice. The sentence "Actually the proportion of A<sub>2</sub> is the same in A and AB—about one . . ." should read "Actually the proportion of A<sub>2</sub> is nearly the same in A and AB—about one . . ."

## BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 22 1944

## EPIDEMIOLOGY OF SCARLET FEVER

The greater prevalence of scarlet fever last autumn has led to some quickening of interest in an infection which the younger generation of medical men regard as among the milder of childhood fevers. Those whose memories go beyond the turn of the century, however, learned to have a wholesome respect for scarlet fever, and, despite an 85% reduction in fatality during the past 50 years, they still wonder if the virulent form of the infection will return. The occurrence of rather serious outbreaks of scarlet fever in certain parts of Rumania from 1934 to 1938 led to a fear that the severity of the disease was, in fact, on the upgrade, and encouraged the International Health Division of the Rockefeller Foundation to send an American team of workers to study its epidemiology in that country. The studies were centred round the town of Jassy, and the populations of four villages 3 to 34 miles distant from the town were chosen for intensive investigation. A public health nurse was resident in each village and visited every household over a month, while a medical member of the team visited the village at least twice a week. Once a month about 10% of the village population had their throats swabbed; a Dick test was done on all available inhabitants once a year, and blood for anti-streptolysin tests was taken from all contacts and patients with streptococcal infection. Haemolytic streptococci isolated from throat swabs were tested for Lancefield group, and, if Group A, were further examined for Griffith type. During the 3½ years of the study, interrupted by the war, scarlet fever broke out in only one of the four villages. The observations on this outbreak linked with the great mass of interesting data from the four centres have shed fresh light on the epidemiology of streptococcal infection in general and scarlet fever in particular.<sup>1</sup>

The occurrence of scarlet fever in epidemic form is determined by a variety of factors—e.g., environmental conditions, the nature and prevalence of the infecting organism, and the distribution and resistance of the host-population. Some of the components are measurable; others are not. Of environmental factors, climate and season are both important, for the disease is unknown in the Tropics, and its incidence has a rough relation to the latitude of a country; though why the tropical peoples should be unhappy breeding-grounds for the streptococcus is still unknown. Seasonally, scarlet fever is a disease of late autumn or early winter, rising steeply in September and October to reach its peak in November or December. This seasonal increase has no relation to the occurrence of respiratory catarrhal infections, but seems to be closely linked with the reassembly of schools. Preceding the

seasonal wave of clinical infection goes a corresponding rise in the streptococcal carrier rate, as Straker and his colleagues<sup>2</sup> noted for London, and as the American workers have confirmed in Rumania. This antecedent carrier wave has been noted in other epidemic infections such as cerebrospinal fever and lobar pneumonia, and where there is a large variety of serological types of the infecting organism (as with the pneumococcus and streptococcus) it affects particularly the epidemic strain. Griffith<sup>3</sup> noted this same fact of a particular strain of haemolytic streptococcus suddenly assuming epidemic propensities in a boarding school, but so far no explanation has been given for the phenomenon. An increased carrier rate of the epidemic strain is not always followed by an outbreak of clinical infection. Other points about streptococcal carriers that emerge from the Rumanian studies are that those under 20 years of age are more likely to be carriers than older people, and that, although Dick-positive and Dick-negative children are equally likely to be carriers, Dick-positive adults are about 50% more likely to harbour the streptococcus than are Dick-negative adults. This last point may give some encouragement to the immunization of nursing staff against scarlet fever.

No one would now deny that the haemolytic streptococcus is causally related to scarlet fever, but that there is no special scarlatinal streptococcus perhaps still needs to be emphasized. The American workers collected scarlatinal strains from many countries and found a great variety of serological types among them, with, as a rule, one or two predominant in each country. Thus, Type 1 was most common in Denmark, Hungary, Italy, Portugal, Turkey, China, and Scotland; Type 2 in Norway; Type 3 in Germany; Type 6 in Finland; Type 10 in Rumania, Bulgaria, and Greece; and Type 17 in Latvia and Australia. The types of streptococcus causing scarlet fever are also commonly found in other streptococcal infections, though these are disease-producing streptococci which are incapable of causing scarlet fever. Both scarlatinal and non-scarlatinal types are also found among symptomless carriers, and the number of cases of scarlet fever with which a particular strain of haemolytic streptococcus is associated will depend on the degree of dispersal of that strain throughout the community.

Turning to the host, the American observers believe that susceptibility to scarlet fever depends on two factors—an antibacterial and an antitoxic resistance. The Dick test, which measures immunity to the erythrogenic toxin of the streptococcus, is ordinarily regarded as the test of susceptibility to scarlet fever, and it is true that infection rarely occurs in Dick-negative persons. But in Rumania 44% of Dick-positive persons who became infected with the epidemic scarlatinal strain failed to develop any clinical illness, and the authors postulate an antibacterial immunity which presumably protected the individuals against a local throat invasion by the streptococcus. Instances of medical and nursing staff developing scarlet fever after 10 years or more intimate contact with the disease spring to mind. Evidence of infection with the streptococcus as shown by a rise in antistreptolysin titre occurred not only in

<sup>1</sup> Schwentker, F. F., Janney, J. H., and Gordon, J. E., *Amer. J. Hyg.* 1943, 38, 27.

<sup>2</sup> Straker, E. A., Hill, A. B., and Lovell, R., *Rep. Ministry Hlth.*, London, 1939, No. 90.

<sup>3</sup> Epidemics in Schools, *Spec. Rep. Ser. M.R.C.* No. 227, London, 1938.

clinically infected persons but also in apparently symptomless carriers, and even in those from whom no streptococcus was isolated. Failure to recover the streptococcus by throat-swab culture does not, of course, preclude its presence, as it may be deep in the tonsillar crypts.

Summing up, and keeping in mind the many variables, we may suppose that the result for the host of contact with scarlatinal streptococcus will depend on whether he does or does not possess antibacterial and antitoxic immunity. If he has antibacterial immunity he may either throw off the streptococcus or become a symptomless carrier; if he has antitoxic but no antibacterial immunity he gets tonsillitis; if he has neither he develops scarlet fever.

## INFANT MORTALITY IN SCOTLAND

The infant death rate in Scotland is greater than in England and Wales, any British Dominion, or the U.S.A., and higher than in the majority of the countries in Western Europe. This adverse position is due to the slower improvement that has been effected in the rate for Scotland than in other countries. The decrease in infant mortality began in several countries some years before the rate started to decline in Great Britain. Since 1896-1900, when the infant mortality in Scotland was 130 and that of England and Wales 156, there has been a steady decline, and in 1936-40 the rates had fallen to 76 and 55 respectively. A much greater improvement during this period was shown by Holland, where the rate fell from 151 to 37. An inquiry into the possible factors which determined the high level of Scotland's infant mortality has been instituted by the Department of Health for Scotland.<sup>1</sup> The report has four main sections: the mortality of live-born infants, stillbirths, the feeding of mothers and infants, the medical services.

When a comparison is made with England and Wales a large part of the excess mortality in Scotland is found to be contributed by infants aged 1-12 months. The death rate under 1 month (neonatal mortality rate) during 1936-40 was 37 in Scotland and 29 in England and Wales, and for 1-12 months it was 39 and 26. The rates for both countries were very high when compared with New Zealand and Australia, where the rates were 23 and 27 for under 1 month and only 10 and 12 for 1-12 months. The infant mortality rate for geographical divisions varies considerably. The highest rate in Great Britain during the quinquennium 1934-8 was that for West Central Scotland with a figure of 88, while fairly low values were found in the Highlands and Islands. The difference between the mortality of cities and rural districts in Scotland, 86/65, was larger than in England and Wales, 65/50. The experience of Scotland is dominated by that of the city of Glasgow, where over a quarter of the total births of the country are registered. This city has the largest infant mortality of all the cities of Great Britain: during 1934-8 it was 99; the second largest rate was Sunderland, 80. Edinburgh, with a rate of 66, compared favourably with cities in England and Wales. During the first month of life the chief causes of death are prematurity, congenital debility, malforma-

tions, and injuries at birth, while during the succeeding months half of the deaths are due to infections. The high infant mortality in Scotland is largely due to a smaller reduction under this heading than has been effected in other countries. Among the factors associated with a high infant mortality the report considers climate, economic and environmental conditions, birth rate, and illegitimacy. The severe winter of the industrial central area may have an adverse effect on child life, but in general there is no evidence that there is an association between infant mortality and climate. Norway and Sweden have mortalities considerably below that of Scotland. There appears to be some relation between mortality at ages 1-12 months and overcrowding and unemployment when the twenty-four large burghs of Scotland are considered, but the association is not large. Glasgow had the highest rate, but nine of the other burghs had a bigger overcrowding index, and five had a greater proportion of the insured population unemployed. Dumfries, with a very low overcrowding and unemployed index, had the third largest rate. In England and Wales there is an inverse relation between infant mortality and social class; though data are not available, this is probably true for Scotland. No large-scale inquiry has been held, but the available evidence shows that infant mortality is correlated with the birth rate. A high birth rate is associated with very early and very late child-bearing and rapidity of breeding—factors that have been shown to have an adverse effect on the chance of surviving the first year of life. Babies are generally infected by their elder brethren of school age, and the later ranks of births have a higher mortality from infectious diseases than the first. A minor factor in determining infant mortality is the size of the illegitimate birth rate. The illegitimate mortality is considerably higher than the legitimate: in 1940 the rates were 120 and 76 in Scotland and 82 and 55 in England and Wales. The percentage of illegitimate births was 6 in Scotland and 4 in England and Wales.

Stillbirths have been registered in Scotland only since 1939, and so far as comparisons can be made there is an excess similar in proportion to that found for mortality during the first month of life. The stillbirth rate tends to be high in the areas where infant mortality is high, but the correlation is probably not large. In the four cities Glasgow, Edinburgh, Dundee, and Aberdeen, during 1939-42 the infant mortality was 95, 64, 77, 74, and the stillbirth rate was 44, 39, 46, 36. No national statistics are yet available for stillbirths by occupation or social class, but small-scale investigations have indicated that possibly the working class have a higher rate than the highest income groups. The returns for England and Wales show that the stillbirth rates are greatest among the first births for all ages of mother, and the rates increase with age of mother and parity after the second birth. The cause of death was unknown or ill defined in one-third of the Scottish stillbirths, but 40% of the total stillbirths could be attributed to hazards of birth and 60% to abnormalities pre-existing in the mothers. During 1938-42 the stillbirth rate in Aberdeen hospitals was 30 per 1,000 births; only 20% were due to hazards of birth, while 80% were due to pre-existing conditions. This small-scale observa-

<sup>1</sup> *Infant Mortality in Scotland*. H.M. Stationery Office. (Is. 3d.)

tion suggests that better ante-natal care would lower the general rate.

The effects of feeding of mothers and infants have to be inferred from rather small investigations, but in the larger investigations covering the general population there is evidence that the adequacy of diets is correlated with economic status. The report suggests that the proportion of inadequately fed mothers in Scotland is high, and because of this there is an excess of unsatisfactory lactations of short duration. The artificial feeding of infants is not satisfactory, from either the hygienic or nutritional standard. Scotland has lagged behind in the provision of maternity and child welfare services. The ratios of ante-natal clinics to births and child welfare clinics to births were in 1937, 1 to 481 and 1 to 336 in Scotland, and the corresponding ratios in England and Wales were 1 to 370 and 1 to 182. The incidence of infections in Scottish maternity hospitals is high. These hospitals are overcrowded, especially the voluntary hospitals, due to a tendency for a larger proportion of mothers to have their confinement in an institution. Among the conclusions reached in the report are that a substantial reduction in the infant mortality of Scotland can be achieved by improving the social and environmental conditions; by enlarging and improving the child welfare services, including the instruction of mothers in infant feeding and hygiene, and the urging of the importance of breast-feeding; more maternity hospitals, and a bigger place in the medical curriculum for teaching of child health and nutrition; and post-graduate courses for family doctors in these subjects.

The above cool analysis of the problem sticks to facts and the inferences to be drawn from them. But when we compare the infant death rates of Great Britain with those of Holland, New Zealand, and Australia, and when we set Glasgow's rate of 99 against England's rural rate of 50 and Edinburgh's rate of 66 during the same period, we cannot help feeling that there is something sadly wrong with our present-day society that such depressing disparities are allowed. A hundred years ago Oliver Wendell Holmes had what he called "my battle for the poor poisoned women." The battle must be renewed—and for the "poor poisoned infants."

## THE NEUROTIC CONSTITUTION

The importance of neurosis in the Services is even greater than its considerable numerical incidence would indicate. As distinct from most physical illness, there is the added cost in terms of endangering others and impairing morale. But although in time of war the problem may appear more urgent and the precipitating factors may be more numerous, there can be no doubt that in terms of social inefficiency it is one of the most important problems of peacetime also. The opportunities for systematic study are, however, far greater in wartime, and it is good to know that they are not being wasted. A recent study by Eliot Slater<sup>1</sup> on 2,000 neurotic soldiers presents facts of great interest to the Services; and as in addition he develops with characteristic clarity a well-constructed general hypothesis based on ingenious methods of analysis, his contribution is of the first importance in both war and peace. The sample, all men, consisted of soldiers with a few sailors and airmen who were admitted to an emergency hospital between

November, 1939, and June, 1941. It thus contains a considerable number of psychiatric casualties of the battles of France and Belgium. The sample is not fully representative. Psychotics, mental defectives, epileptics, and delinquents are under-represented, as they would often be dealt with in other ways. For the same reason there is selection in favour of severity. Nevertheless, the material does give a fair picture of quite a large part of the Army problem.

It is a sobering reflection that Slater has this statement to make: "Very large numbers of these men, who were as a rule useless as soldiers from the beginning, might have been kept out of the Army had they been given even the most cursory psychiatric examination." Nor was the outcome encouraging. Nearly three-quarters of the patients had to be invalided. Of those returned to duty half had to be invalided at any time from a few weeks up to a year. Improvements have, of course, been effected, as regards both initial exclusion and disposal, and it is to be hoped that better results are now being attained. In the matter of disposal it is stated that no matter what treatment is employed the results are the same. The hopeful approach, it is claimed, is not psychotherapy—the adjustment of the patient to his environment—but the converse—the adjustment of the environment to the patient.

Only a few points can be mentioned from a paper that should be studied in full by all interested in the subject. Military stress is found to be especially potent in producing anxiety and also hysterical symptoms and amnesia. Many men suffering from anxiety states are of good constitutional type; the breakdown would have been difficult or impossible to predict and the prognosis is relatively good. Even here, however, constitutional make-up is still of major importance, while in some other groups—for example, the obsessionals or the psychopaths—breakdown has little or no relation to stress. It is noted that there are profound differences—highly significant statistically—between the endogenous and the reactive depressions as regards frequency of association with childhood neurosis, previous nervous breakdown, anxious traits, and pyknic habitus. Slater also notes how easily the predisposed individual becomes conditioned to such things as dive-bombing, and remarks that there is plausibility in the view that the plastic mind of the child is even more susceptible. The general hypothesis is summed up thus:

"Neurosis represents a special case of a generalized type of behaviour, and signifies a failure of adaptation. The two primary reagents are the individual constitution and the environmental set-up of the moment. The individual constitution is in greater part determined by hereditary factors, to a lesser degree by environmental circumstances of the past producing their effects by organic lesion and psychological and physiological conditioning. These factors, especially the first, determine the form and the severity of the congeries of symptoms which are the so-called neurotic states or neuroses. The momentary environment determines the time of manifestation, and to a lesser extent the severity and even the form of the symptoms (e.g., the association of military stress and anxiety). Other factors, such as physical illness or physiological upset and intellectual incapacity, can have an adjuvant effect, and may also influence the form of the reaction (e.g., mental defect in favouring hysterical manifestations, physical illness in favouring hypochondriasis). . . . There is little to be said for the convention by which certain traits, such as aggressiveness and asocial tendencies, are regarded as psychopathic, whereas tendencies towards anxiety, instability of mood, dissociation, etc., are regarded as neurotic. If we wish to introduce system and reason into our nomenclature it will be necessary to discover further traits showing the degree of specificity and independence that obsessiveness seems to show. . . ."

This hypothesis is put to the ingenious test of a "factor-analysis" analogous to those tests familiar to the educa-

<sup>1</sup> *J. Neurol. Psychiat.*, 1943, 6, 1.

tional psychologist. Within the limits of the statistical methods employed, and in view of the inevitable errors of observation, the test proves to be highly favourable to the hypothesis. The double assumption of a neurotic constitution and a poor intelligence accounts for more than 90% of the observed variability. If it is true that hitherto intelligence has been considered too exclusively in quantitative terms it would seem to be even more true that far too qualitative a view has in the past been taken of temperamental traits. A recognition of the quantitative aspect of neurotic tendencies may well lead to a clearer understanding and to important advances in knowledge.

### LIPHOPHAGIC GRANULOMATOSIS

Numerous terms have been proposed for a pathological process, usually seen in localized fatty tissues, whereby phagocytosis of fat droplets by giant cells sets up a cellular granulomatous condition in which fibroblasts, leucocytes, and other cells take part. Such granulomata have been described in the breast, subcutaneous tissues, and mesenteric fat depots, and appear to result from some local fat necrosis with liberation of lipolytic ferments and subsequent foreign-body reaction of the neighbouring tissues. Besides such local lesions a rare but apparently identical histological condition is seen now and then in which the changes occur in the inner coats of the small intestine and involve the mesenteric lymph nodes. S. Sailer and R. J. McGann<sup>1</sup> have described such a case and reviewed the literature of this subject without, however, precisely defining either the aetiology or the symptomatology, but adopting the title "lipophagic granulomatosis." In their case post-mortem examination showed massive lipophagic granulomatosis of the abdominal lymph glands, and infiltration of the mucosal villi of the small intestine with large foamy mononuclear cells and giant cells. The colon was unaffected, but most of the small intestine showed these changes, which spread into the muscularis mucosae and were associated with much general cellular infiltration. Stained with scarlet red and osmic acid, these large cells gave the reactions for neutral fat, as did cells in the adjoining lymph nodes. Clinically the patient was observed for a period of two years, during which time he suffered from abdominal pain, weakness, loss of weight, and anorexia. The abdominal pains were worse after eating but were almost constant during the day. There was no steatorrhoea. A moderately severe hypochromic anaemia developed which did not respond to treatment, including blood transfusion. A terminal peritoneal effusion occurred and an acute bronchopneumonia. Some other cases in the literature have shown a polyarthritis. Of the various explanations put forward to account for these remarkable pathological changes none is wholly satisfactory. Lymphatic obstruction causing stasis and backflow of chyle in the intestinal lacteals seems to be ruled out. Whipple<sup>2</sup> suggested that the fat absorbed in the intestine became in some way abnormal or possessed some toxic property, in view of the process being limited to the structure concerned with fat absorption, while lymphatic tissues elsewhere were practically normal. Others have postulated some disturbance of pancreatic lipase secretion whereby the intestinal fat is abnormally split and the absorbed abnormal products provoke a foreign-body response in the intestinal mucosa. Whatever may ultimately prove to be the explanation, accounts of such unusual and striking changes deserve careful study, because it is often through such apparent errors in metabolism that light is thrown upon normal processes.

### TUBERCLE BACILLI IN MILK

One of the proposals in the Government's White Paper on milk policy, discussed in our issue of Aug. 7, 1943, is to define scheduled areas within which no milk shall be sold unless it is adequately heat-treated, tuberculin-tested, or "accredited" coming from a single herd. The wisdom of this last exception has been questioned in a number of quarters. Figures recently collected by Sir William Savage show that the proportion of samples of "accredited" milk found to contain tubercle bacilli was almost consistently higher than that of ungraded raw milk. The danger of allowing "accredited" milk to be sold raw is aggravated by the present state of the law, which makes no provision for the stoppage of the infected milk supply. Under the Tuberculosis Order a cow suffering from a tuberculous udder must be condemned, but mixed milk shown by bacteriological examination to contain tubercle bacilli may continue to be sold. What happens in practice when tubercle bacilli have been demonstrated in the milk of a given herd is that the local medical officer of health informs the county medical officer, who, in his turn, passes the information on to the divisional veterinary inspector of the Ministry of Agriculture. Nothing more is then heard by the health authorities until a notice is received, usually two or three months later, that the tuberculous cow has or has not been found and that the milk is now free from tubercle bacilli. This mechanism is cumbersome, laborious, and time-consuming, and fails to protect the public in the meantime from the risk of drinking tuberculous milk. In his report for the years 1939 to 1941 Dr. G. G. Wray, M.O.H., Fulwood Urban District, suggests the following alternative procedure: (1) Compulsory notification, under heavy penalty for non-compliance, of tuberculosis in cattle; (2) provision of free veterinary inspection immediately on notification; (3) prohibition of the sale of milk from the farmer till after adequate heat treatment, the producer to be guaranteed against any monetary loss on the sale of this milk; (4) payment to the producer of a fee for notification, and of compensation equal to the full market value of the cow after the animal is slaughtered; (5) authorization for the local authority to provide a heat-treatment plant itself or to license a local commercial plant for this purpose; (6) responsibility for the efficient discharge of the whole scheme to be placed on the local authority. It is believed that this alteration in procedure, by placing the responsibility for action on one authority instead of three, would obviate the defects of the present system.

Attractive as this scheme may appear at first sight, it is doubtful whether it would work out satisfactorily in practice. In the first place, very few farmers could be expected to diagnose udder tuberculosis themselves. Even after tubercle bacilli have been demonstrated in the mixed milk of a herd a skilled veterinarian may have great difficulty in finding the infected cow, and often has to have further bacteriological examinations carried out before his search is successful. Secondly, how is free veterinary inspection to be provided by a small local authority? Is the authority to call in a private veterinarian, or is it to command the services of the Divisional Veterinary Inspector, who, it will be remembered, is a whole-time servant of the Ministry of Agriculture? Again, would it be economical for a small local authority to install pasteurizing equipment for the milk of a single herd, and who would be qualified to run it? Other difficulties might be raised. Nevertheless, the contention that raw milk known to contain tubercle bacilli should not be allowed to be sold in the liquid market is absolutely sound, and it is to be hoped that in the new Milk Bill such a prohibition will be incorporated.

## THE LATE DR. G. C. ANDERSON

## MESSAGES OF CONDOLENCE

The British Medical Association has received messages of sympathy on the passing of Dr. Anderson from all parts of the country and from many parts of the world. The Minister of Health in a letter to Lord Dawson, the President, says with what "very real regret I have heard of the death of Dr. Anderson, and I should be grateful if you would convey my personal sympathy to the officers and members of the B.M.A. I have heard much of the wise and courageous advice with which for so many years he helped my predecessors. . . I fear we have lost a man whose services at this time could be invaluable."

The following message has been received from the Registrar of the Royal College of Physicians of London: "The Council of the Royal College of Physicians desires to convey to the British Medical Association its sense of the great loss sustained not only by the Association but by the whole profession of medicine in the death of Dr. G. C. Anderson, whom the College was happy to count among its Fellows. His wide knowledge of the conditions of medical service, his statesmanlike qualities, and his great gifts as a negotiator will be sorely missed, and the Council wishes to place on record an expression of its sense of the irreparable loss which the profession has sustained, and its sympathy with the British Medical Association in the loss of so able and so devoted a Secretary."

Tributes have come from the Federal Council of the Association in Australia, the Canadian Medical Association, the New South Wales Branch, South Australian Branch, and Victorian Branch, and the Jamaica Branch; from many Local Medical War Committees, Divisions and Branches of the Association, and Local Medical and Panel Committees. Messages of sympathy have been received from the Medical Branches of the Service Departments, the Medical Personnel (Priority) Committee, Medical Association of Eire (I.M.A. and B.M.A.), the Medical Women's Federation, Medical Association of South Africa, Editor and Staff, *South African Medical Journal*, Society of Medical Officers of Health, Medical Superintendents' Society, Association of Clinical Pathologists, British Hospitals Association, Voluntary Hospitals Committee for London, British Hospitals Contributory Schemes Association, Merseyside Hospitals Council, British Dental Association, National Association for the Prevention of Tuberculosis, Royal College of Nursing, Pharmaceutical Society of Great Britain, British Social Hygiene Council, National Ophthalmic Treatment Board, Central Office for Refugees (Medical Department), Central Council for Health Education, the London Hospital, the Westminster Hospital, the honorary medical staff of the East Surrey Hospital, Royal Society for the Prevention of Accidents, Joint Committee of Approved Societies, National Association of Insurance Committees, National Association of Clerks to Insurance Committees, Rotary International, British Medical Finance, Ltd., the Advertising Association, as well as from many individual colleagues and friends.

Mrs. Anderson has received a very large number of letters of sympathy from individual friends in the profession and from committees with whose work her husband was closely associated. She is very grateful for the kind thoughts of all, though it will be appreciated that she finds it impossible to reply to each personally. She hopes that medical friends and colleagues will take this note as an expression of her gratitude for the sympathy so widely expressed to her in her loss.

By an oversight the name of Dr. C. L. Batteson, who represented Epsom College and the London Panel Committee, was omitted from the list of those attending the memorial service at St. Pancras Church, and published in last week's issue.

The Hospital Saving Association has just paid £171,743 to the London voluntary hospitals as a final distribution. This brings the total for the year to £600,193. Once again it has been calculated at 9s. per day for every H.S.A. in-patient and 7s. 6d. for each out-patient. This brings the total distributed by the H.S.A. during its 21 years' existence to just short of ten million pounds. All this money has been collected by voluntary workers, of whom there are now some 13,000 in the Greater London area. The number of H.S.A. groups and contributors is steadily growing.

## CANCER RESEARCH: A COMPLEX PROBLEM

The Duke of Gloucester, in presiding over the annual meeting of the British Empire Cancer Campaign, now in its twenty-first year, spoke of his approaching residence in Australia as Governor-General. He said that this would not mean for him a severance from the Campaign, which is represented by a Branch and by several affiliated organizations in the Commonwealth. The Duke also announced that the trustees of the Bernhard Baron Charities Fund had, for the second time, allocated to the Campaign the sum of £10,000, on this occasion for the establishment of a cancer research fellowship.

The adoption of the annual report—a document almost up to pre-war size—was moved by Prof. E. C. Dodds, F.R.S., who gave a picture in brief of "cancer research as it really is." The whole technique of pathology and biochemical research, he said, had been changed by the introduction of new methods, such as the use of isotopes in studying metabolism, the ultracentrifuge and electron microscope in the study of the form and structure of matter, and the introduction of the cyclotron in the study of matter from the physical aspect. The technical use of these and other instruments required new and deep knowledge of a most complex character, in addition to the knowledge of the problem to which the instruments were applied.

The cancer research worker of the past, said Prof. Dodds, stood no chance of making any fundamental discovery because he was handed a problem far too intricate and complicated in view of the development of his intellectual and scientific processes. It was as though one of the classical Greek philosophers were faced with a modern motor-car engine. All the sciences necessary to its understanding—electricity, magnetism, chemistry, metallurgy—were unknown to him. To-day the research worker in cancer had to start from the beginning. The vast amount of knowledge already accumulated was valuable in plotting out the mountain peaks, but he had now to start on the details, which would take time, though the future looked more certain than ever before.

## Synthetic Oestrogen for Cancer of Prostate

Speaking as one of "the back-room boys" or laboratory workers in the chemical field, Prof. Dodds said that it was with particular pleasure he drew attention to one positive result—namely, the treatment of malignant disease of the prostate with synthetic oestrogens. The American work on the treatment of this disease by the administration of substances by mouth, and the subsequent complete disappearance of symptoms, had been wholly confirmed, and "for the first time in the history of mankind it is possible to state that one form of cancer can be completely controlled and the patient rendered symptom-free by the administration of a few pills by mouth each day."

In the annual report of the Campaign further reference was made to this substance, diethylstilboestrol, the usefulness of which, it was stated, seemed to be restricted to cancer of the prostate, though, even so, a new line of research had been opened up along which in the near future many workers were sure to pass. The substance is a synthetic chemical product resembling a number of glandular products, and possesses many chemical affinities, all of which, in course of time, will be brought under examination.

## Carcinoma in Other Sites

The report also records the work of the Campaign's Clinical Research Committee, which this year presents a detailed analysis of over 1,000 cases of primary carcinoma of the lung. The investigation confirms the finding that cancer of the lung is much more common in males than in females, and it shows that engineers, mechanics, painters, and decorators are more liable to it than other occupational groups—for example, clerks and typists. The difference is said to be statistically significant, but it has to be borne in mind that the average age of the cancer patient is higher than that of the census population, and many clerks and typists change their occupation before reaching the cancer ages.

Some work is quoted from the cancer research committee of the Marie Curie Hospital suggesting that the cervix uteri is one of the sites of cancer in which great improvement might

be expected in the number of cures if intensive propaganda leading to earlier diagnosis were undertaken. Irregular haemorrhage at the menopausal and post-menopausal periods may be significant, and yet it is apt to be regarded by the patient herself as a natural phenomenon, and medical advice is sought only when symptoms become urgent. In the radiological field the work at St. Bartholomew's cancer research department is reported as suggesting that certain types of cancer are curable by high-voltage x-ray therapy (of the order of 1,000 kV), where x-ray therapy of the order of 200 kV produces at most a temporary palliation of symptoms.

Important investigations are being carried out both in London and in the provincial centres of the Campaign with the aid of the substance known as benzpyrene. In spite of threatened shortage the Campaign has been supplied with quantities of pyrene, from which benzpyrene is convertible. The substance figures in the reports from several centres, particularly in the study of the induction of skin cancers in mice. The editing of the report is again the work of Mr. J. P. Lockhart-Mummery, who has undertaken this task now for twenty successive years.

## Nova et Vetera

### THE HISTORICAL MEDICAL MUSEUM

At a recent meeting of the Section of History of Medicine of the Royal Society of Medicine, Sir WALTER LANGDON-BROWN presiding, Dr. S. H. DAUKES, director of the Wellcome Museum of Medical Science, lectured on the future and possibilities of the Historical Medical Museum. The lecture was accompanied by a large model of one of the ten halls of the Wellcome Historical Medical Museum, which is in process of reconstruction, and by an exhibition of rare books from the Wellcome collection. These included a number of first editions, notably a first edition containing all the chief works of Malpighi and a first edition of Morgagni's *De Sedibus*. Over forty works were displayed, and it was stated that fewer than half of them were to be found in the libraries of the Royal College of Physicians or the Royal Society of Medicine.

Dr. Daukes said that a museum must be a living thing with a message, not a valley of dry bones. Too often museums were treated as mausoleums, when they ought to be schools for the creation of ideas and exhibits of raw materials from which those ideas were formed. He liked the definition of a good museum: "Instructive labels illustrated by well-selected specimens." The Wellcome Historical Medical Museum was founded by Sir Henry Wellcome and opened by Sir Norman Moore in 1913. It was unfortunately arranged. There were two types of collector, one who spread a net and the other who used a rod and line, and Sir Henry Wellcome belonged to the former category. He detected some possible value as a museum exhibit in most insignificant objects, with the result that his collection became gigantic—there seemed to be enough weapons from all over the world to arm the Home Guard! His books and MSS. ran into half a million. The crude exhibition at Wigmore Street represented only a small part of the total collection and was never intended to be more than temporary.

#### Plans for Future Display

After Sir Henry Wellcome's death in 1936 it became necessary to examine the material critically, and Dr. Daukes said that, having himself been responsible for the Wellcome Museum of Medical Science, he was given the task of arranging the historical museum on permanent lines. It was desired to preserve the identity of both museums, but to link up their activities. The space available for the Historical Medical Museum consisted of ten large halls on three floors, each hall measuring 110 by 40 feet. The exhibits would be arranged in an order partly cultural and partly chronological as follows:

- I. Cosmogony, palaeopathology, evolution of man, prehistory.
- II. Primitive medicine of all ages, Mexican and Peruvian medicine.
- III. Medicine of Ancient Egypt, Chinese and Indian medicine.
- IV. Greek, Alexandrian, Graeco-Roman, and Byzantine medicine.
- V. Mediaeval medicine.
- VI. Renaissance to end of seventeenth century.
- VII. Eighteenth and part of nineteenth centuries.
- VIII. Nineteenth and twentieth centuries.
- IX. History of diseases (to link up with modern museum).
- X. Central hall with library for reference and research.

In each hall—of course with modifications according to the era—the sequence would be:

Contemporary history as affecting the medicine of the period; general survey; chemistry (or alchemy) and physics in relation to medicine; physiology; anatomy; surgery; medicine, including aetiology (bacteriology, etc.); pathology; clinical aspects, and treatment (rational, superstitious, folklore, etc.); education and hospitals; prevention (social medicine).

It was hoped to have two floors ready within a year of the cessation of hostilities in Europe, and the remainder would be opened hall by hall as it was completed. An elaborate system of labelling and cataloguing would be arranged, and explanatory summaries of the exhibits would be kept up to date. Literature was the backbone of history, and books, MSS., and letters would be freely used as museum exhibits. As a rule literature was used to elucidate the objects; here also the objects would be used to elucidate the literature. Each section so far as possible would convey the atmosphere of its period by large-scale models and tableaux, including, for example, reconstructed pharmacies. There was too much inclination to judge the past in the light of present knowledge; it was necessary always to judge of achievement by contemporary history. Much of Sydenham, for instance, in the light of modern knowledge, would be accounted nonsense, but in the light of contemporary knowledge it was most wise. It was deplorable that younger members of the profession took so little interest in the history of medicine. Teachers might use a few historical details as a kind of *hors d'œuvre* to their lecture, but more than this was necessary; the historical background ought to have a closer practical application. It was hoped that the resources of the new museum would be freely used for illustrating papers and for loans to exhibitions. Thanks to the beneficence of the founder, funds were available for carrying out the scheme.

#### Function of a Museum

Dr. Ashworth Underwood said that Sir Henry Wellcome had much in common with Sir Hans Sloane and John Hunter. All three were great practical men in other fields than museum-making and all three were great collectors, but Wellcome alone was able to provide completely for the future of his collections without the help of State or university. Dr. F. Parkes Weber said that it was high time there was such an undertaking. Careful thought should be given to what was included in a museum of medicine. In his view a Wedgwood medallion of Hippocrates, however interesting as an object of art, had no value in medical history. He would prefer a copper coin from Cos with a portrait of Hippocrates, though that, of course, would not be contemporaneous.

Sir Frederick Kenyon, formerly Director of the British Museum, urged the need for a lecture theatre in association with a museum. He was of opinion also that not all the material should be in the "show window." Sir John Forsdyke, keeper of Greek and Roman antiquities at the British Museum, said that Wellcome's was the best method for the formation of a museum—namely, the accumulation of an abundance of material, with the opportunity of discarding what was not needed, rather than the opposite plan seen in many municipal museums which started with empty shelves. Mr. Arundell Esdaile, secretary of the British Museum, said that there was a great charm about a fortuitous concourse of objects, because it was possible to select from them what was wanted, and nearly always to find a good home for what was not.

Dr. Daukes, in reply, said that there would be an extremely fine lecture hall attached to the museum. He agreed that it was desirable only to show exhibits which answered the immediate purpose, while others were stored and brought out as required, and this plan was being followed. The question of the ethnographical section was being considered very carefully in order to see how far it bore on the history of medicine and how much of it could be allocated to other museums. The Wellcome Museum would be for students in the broadest sense of the word. It would be arranged in bays, so that the student could pursue his work in relative detachment, and portable chairs and tables would be provided which he could carry with him from bay to bay. But it was not intended to provide a peep-show for any casual passer-by on the Euston Road.

The medical teaching film on the diagnosis and treatment of scabies made by the Ministry of Information at the request of the Ministry of Health has been widely shown and has already proved successful. In three months it has been shown by means of the mobile units of the Ministry of Information to 254 separate audiences totalling 21,326 doctors, nurses, and other personnel interested in the subject of scabies, and copies have also been lent out to others who had the use of projectors. A second shorter film, lasting 7 minutes, called "The Scabies Mite," has just been made as a specialized scientific film for specialist audiences. Without touching on the subject of the diagnosis and treatment of the disease it incorporates the photomicrography of the longer film to give a full explanation of the life cycle of the acarus. Particulars of the arrangements which can be made for the exhibition of these films may be had from the Ministry of Information Regional Offices or from the Central Film Library, Imperial Institute, South Kensington, S.W.7.

## Reports of Societies

### CROSS-INFECTION IN FEVER WARDS

At a meeting of the Fever Group of the Society of Medical Officers of Health on Dec. 17, 1943, with Dr. ANDREW TOPPING in the chair, Dr. R. B. BOURDILLON opened a discussion on the control of respiratory infections.

An average vigorous sneeze, Dr. Bourdillon said, emitted 100,000 bacteria-carrying particles, of which in still air about 4,000 would remain suspended half an hour later. Talking emitted fewer particles, the number varying with different people. For three different laboratory workers reading out loud, the total number of infected particles collected per minute was 1,500, 250, and 75 respectively. About half of these were large enough to collect on open Petri plates. A number of different patterns of masks were then shown.

Dr. JOYCE WRIGHT reported the results of an investigation into the control of dust-borne infection in measles wards. In a test ward, in which for three weeks the floor alone was oiled, the haemolytic streptococcal content of the ward air during bed-making was but slightly less than that of a control ward. During this time, and throughout the work, the majority of the aerial streptococci were Type 6. Among the patients' the cross-infection rate with Type-6 streptococci was 58.1% in the test ward and 53.3% in the control ward; the middle-ear complication rate due to Type-6 cross-infection was 18.4% in each. As oiling the floor was evidently not enough to control cross-infection, further measures of dust control—by treating blankets, sheets, patients' garments, etc., with technical white oil—were introduced into the test ward. During the subsequent nine weeks the mean haemolytic streptococcus count in the air of the test ward during bed-making was reduced by 97.5%. Compared with the control ward, the mean bacterial count in the air during bed-making and sweeping was 91% less in the test ward, and the mean haemolytic streptococcus count was 98 to 99% less. Furthermore, the Type-6 cross-infection rate was 18.6% in the test ward, while in the control ward it rose to 73.3%. The middle-ear complication rate due to Type-6 cross-infection was 2.8% in the test ward, compared with 14.3% in the control ward. The results suggested that dust was important in the spread of streptococci in measles wards; that the oiling of bed-clothes, etc., and of floors reduced the infected dust in the air; and that, as a result, the cross-infection and complication rates were lowered. Attention should also be paid, however, to the control of droplet spread, particularly by convalescent patients, and of contact spread by toys, books, baths, etc., and by the nasal toilet.

All but a few of the patients in both wards received an intensive sulphonamide course, usually sulphanilamide or sulphathiazole. The cross-infecting Type-6 streptococcus was found by *in vitro* tests to be sulphonamide-resistant. Differing results recorded by various workers on the prophylactic value of sulphonamides in measles wards might be explained by differences in sulphonamide susceptibility of the cross-infecting strains of streptococci.

Dr. H. STANLEY BANKS, in discussing chemoprophylaxis of respiratory complications, said that the case-fatality rate of measles in the Park Hospital had fallen from 6.3% of 1,290 cases in 1933-4 to 0.3% of 1,625 cases in 1942 and 1943. There was a parallel but less pronounced fall in the incidence of bronchopneumonia, which was chiefly due to the almost total abolition since 1940 of bronchopneumonia occurring after admission. This change exactly concurred with the operation of a scheme of prophylaxis by sulphapyridine for 5 days from admission. Another apparent effect of this chemoprophylaxis was seen in the steep fall in incidence of suppurative otitis media after admission from 13.6% in 1933-4 to 3.8% in the closely corresponding epidemic of 1943. Further analysis showed that this reduced amount of otitis media was with few exceptions in the period after the ninth day from admission—that is, after the chemoprophylaxis had ceased to operate. Such otitis media as there was therefore presumably came from ward cross-infections, manifesting themselves clinically when chemoprophylaxis ceased. To reduce these infections to the lowest level the period of isolation in open wards should be as short as

possible in all uncomplicated cases—e.g., 12 days. Chemoprophylaxis might be extended for longer than five days, but this introduced certain difficulties. But prompt and adequate chemotherapy of these cases of acute otitis media much improved the outlook. The best drug was sulphathiazole and the dosage must be high—as for severe infections—beginning within the first few days—the earlier the better. A course of 9 or 10 days completely cured about two-thirds the cases, and most of the remaining third could be cured a second or even a third course applied without any break after the first. Occasional white blood counts were necessary but young children tolerated the drug remarkably well. More than 90% of the cases recovered within 3 weeks. In the few years of this experiment there had been only four mastoid operations—one each year—whereas in 1938 there had been 19 mastoid operations in the hospital. By means of chemoprophylaxis, chemotherapy, sharp clinical supervision, and isolation periods, morbidity from streptococcal cross-infection could be kept very low even under present working conditions in open wards. These were at least practicable measures. The general use of masks was impracticable, and such measures as oiling of blankets and floors had not yet been proved to be practicable. Dr. Wright's high figures of cross-infections were apt to give a false impression of the magnitude of the problem. They referred only to the peak period of the epidemic and other respects also were exceptional.

Dr. H. J. PARISH thought that spraying with aerosols would not control respiratory infections, as organisms might remain viable for 10 to 15 minutes, during which time infection could take place. He wondered, too, whether oiling of floors and blankets was necessary in modern fever hospitals with good bed-spacing, adequate ventilation, etc. He had seen numerous barriers in use between beds, but was doubtful of their efficiency. Dr. BOURDILLON thought a short barrier opposite the patient's head was an advantage provided the patient could be taught to cough or sneeze directly at it.

Dr. MITMAN said that in combating aerial cross-infection must be realized that hospital air and dust carried a bacterial load enormously in excess of that outside, and that almost all respiratory infections were intramural events. The bacterial load of a room depended on the rates of addition and removal of organisms; measures of control aimed at influencing one or other of these rates. Methods of limiting the rate of addition included the avoidance of overcrowding, observance by individuals of the rules of hygiene, the application of modern architectural and engineering principles to ward construction and the practice of fever-ward management. Guarding the mouth and nose with a big handkerchief during sneezing at coughing should be a cardinal rule of hygiene; masks were merely an extension of this principle. Sneezing into the sleeve should be forbidden as was spitting—a practice now almost eliminated. Those in an infectious state should avoid crowded places and social calls. Dust traps must be avoided in ward construction and furnishing. Medical superintendents should review their hospitals' practice of dealing with blankets after use by a patient. Oiling was only an expedient, and he was convinced that blankets as an article of bed-clothing in hospital wards must go. Only in patients with tuberculosis had the danger of the pocket handkerchief been appreciated. Current methods of removing bacteria, aerosols, ultra-violet irradiation and air-conditioning were still experimental, but ventilation was an old and tried practice of the utmost importance. Wells considered ventilation fair if there are 25 to 100 turnovers per hour obtainable in mild weather with open windows. Fewer than 10 turnovers per hour constituted bad ventilation and was quite common during war if windows and doors were closed and air replacement depended on natural seepage. Good ventilation with a rate equivalent to 100 to 500 turnovers per hour could be obtained only by the use of germicidal ultra-violet lamps irradiating the upper air—equivalent to removing the ceiling and ventilating upwards.

Dr. W. GUNN said there was probably a future for ultra-violet irradiation for checking cross-infection, but not until dust was satisfactorily eliminated, as it protected the organisms from the lethal effects of radiation. The cross-infection and complication rates recorded in Dr. Wright's communication appeared high compared with hospital figures for other measles epidemics but the experiment took place over a short period at the

height of a severe epidemic when some degree of overcrowding could not, for a variety of reasons, be avoided.

In reply to a question, Dr. BOURDILLON said that for hospital purposes with unlimited laundry facilities he favoured the gauze mask provided it was changed frequently. On the subject of ward ventilation he felt that very high rates of air-exchange could not be tolerated by the older patients, who felt much too cold.

## Correspondence

### The Nature of Concussion

SIR,—I was very interested to read Prof. Jefferson's article (Jan. 1) on concussion, especially those parts of it which dealt with consciousness and unconsciousness, my special interest being in the *recovery of memory* in these cases. Medical psychologists are very familiar with cases of traumatic amnesia in which there is no discernible organic change, but in which there is loss of memory, which is recoverable, and, indeed, is often spontaneously recovered. Where is the dividing line between these cases of psychological amnesia and cases of the unconsciousness of concussion? I have come to the conclusion that there is no specific dividing line on the psychological side, a conclusion based on the fact that even in cases of severe concussion the *whole* memory of the experience and accident is recoverable by methods of free association, hypnosis, and narco-analysis. If that is so, obviously whatever happens in concussion is not something which so affects the brain that consciousness is obliterated.

For the space of 18 months in the last war, in a ward of 60 "shell-shock" patients, I paid particular attention to the complete recovery of memory in those cases of concussion (in which there is no discoverable physical injury) as a method of treatment, and never failed to recover the memory of the traumatic experience *in detail*. This has been repeated by many physicians in the interval between the wars in cases of concussion as from car accidents, and in many cases in this war. A recent case is that of an A.R.P. warden, who was blown up in the road during the London "blitz" by two shells one on each side, had amnesia for four days, and for eighteen months suffered from severe headaches, insomnia, and severe pain in his neck, which was flexed on the chest as though broken. The whole memory was recovered of the explosions, the blasts of air, being carried up the height of a suburban house, his thoughts while in the air (that he must at all costs avoid the spiked railings: that he must fall in a way so as to break the fall as he had learnt in wrestling), his crash on his back in a field 20 yards away, the awful jerk of his neck forward as he had his helmet on, lying there thinking he was dead ("So this is death!"), that Tom R. would be coming round to do his gracious job of putting his dead body in his sack; and then his realization he was not dead. He subsequently had a fugue state with loss of memory for four days, during which he wandered about London visiting streets where he had never been before, the names of which he confirmed by visits after his recovery. All these experiences were *relived* and remembered, with the result that he completely recovered and has now started a new business of his own.

The recovery of such lost memories is a familiar technique of every medical psychologist who uses abreaction as a form of treatment. To say, as one writer does, that psychological "amnesia" relates to the part of the experience which we can recover, and "concussion" to what we cannot recover, is to make the diagnosis of concussion depend on the skill and patience of the physician. Failure to recover is usually due to lack of persistence. That these memories are not merely imagined is proved by the fact that the patients subsequently clearly remember these experiences like any other. It is also an interesting fact in contrast with these cases that when the patient is put under an anaesthetic during the period of amnesia, he cannot recover any memories of the surgical operation (as we should expect that he would not); and we have also failed to recover the memory in cases of contusion—such as fracture of skull—these failures acting as a "control," indicating the genuineness of the memories in concussion.

Obviously the "concussed" patient is not altogether unconscious, though he appears to be so; rather he suffers from amnesia. We suggest, however, that in these cases of concussion the patient is in a *low state* of consciousness, which is, therefore, not recalled in the full and lively consciousness of ordinary life. An analogy to such dissociation is found in the fact that we may get up in the night, carry out some routine act like closing a banging door, and yet recollect nothing of it in the morning. We are in a somnambulant twilight state of consciousness, which seems to be the state of the patient with "concussion." The amnesia in such cases may be due to the fact that the experience is on a different level of consciousness, and therefore dissociated from ordinary consciousness, as indeed it is in states of hypnosis. For that reason we welcome Prof. Jefferson's use of the term "stupor," for in a case of stupor the patient can often hear and understand what is said though unable to respond, as is also frequently the case with a patient going under an anaesthetic who hears the remarks of those around. Prof. Jefferson's other term "parasomnia," which he defines as a "state in which there is no response to stimuli, verbal or mechanical, except those of a reflex nature," does not rule out consciousness, for we may be conscious without being able to respond in any way, even reflexly. Lack of response does not necessarily imply lack of consciousness.

Again, Prof. Jefferson says that the muttering of the concussed patient shows that cortical actions continue: it also suggests that consciousness is maintained as our experiments seem to prove. If it is true, as Prof. Jefferson says, that "the beliefs expressed above have minimized the importance of the cortex in the picture of concussion," this also is in keeping with our psychological experiments, which indicate that consciousness and therefore cortical function is maintained in "concussion," though in a low form. So far, Prof. Jefferson's observations support our conclusions. But in so far as Prof. Jefferson is out to prove that, because the cortex is not put out of action, the unconsciousness must relate to some other part of the brain, this is negatived if consciousness is proved *not* to be obliterated.

Indeed, any definition of "concussion" based on the idea that in concussion the brain as a whole or any of it is so put out of action that consciousness is obliterated is untenable, since consciousness seems to persist throughout, and can be recovered.

Finally, the definition of "consciousness" as a state implying "insight" is surely unsatisfactory as a definition, for it defines an unknown by a more unknown, for what is insight but a state of consciousness or awareness of the object: indeed, insight implies more than consciousness, since it also implies awareness of the *meaning* of an object.—I am, etc.,

Psychological Department, King's College.

J. A. HADFIELD.

### Sciatica

SIR,—Prof. Platt's letter (Jan. 8, p. 57) is interesting but not very helpful, because he does not tell us what in his opinion is the common cause of sciatica. Surely there must be at least one common cause for so common a complaint. I agree that true sciatic neuritis is comparatively rare, and that the really common cause of sciatica must be sought elsewhere. It is not to be found in the spinal tumour or in the prolapsed intervertebral disk. Prof. Platt speaks with some enthusiasm of the prolapsed disk and of the rich harvest of cures by removal of the projecting fragment in *cases selected from the large numbers of sciatica patients* who continue to find their way to orthopaedic surgeons (italics mine). The truth is that, in spite of all that has been written and said about it, the prolapsed disk is a comparatively uncommon condition. In the largest series of cases hitherto published (300 cases from the Mayo Clinic) the incidence was 3 to 4% of sciaticas, which means that 96 to 97% of sciaticas are *not* due to prolapsed disks. Visceral pelvic disease is common, but not as a cause of sciatica in orthopaedic practice. Destructive lesions (inflammatory or new growth) of the lumbar spine, pelvis, and femora are not common, if we except tuberculous disease of the hip, which is not a cause of sciatica. Tuberculous disease of the sacro-iliac joint is a definite cause of sciatica, but it is itself a rare disease. Neither sacro-iliac strain nor lumbosacral strain is ever a cause of sciatica. It is curious that, in giving

an example of referred sciatic pain, Prof. Platt should have singled out osteo-arthritis of the hip. This is mentioned as a cause of sciatica in all the textbooks, and it has been copied from book to book for many years. But osteo-arthritis of the hip is practically never a cause of sciatica, although many patients with osteo-arthritis of the hip also have osteo-arthritis of the lumbar spine.

What does it all boil down to? What have we got left? What is the really common cause of this very common complaint? Prof. Platt says that "the causal lesion in a large group of cases is to be discovered in that complex system of articulations embraced by the lumbar spine and the sacro-iliac joints." This sounds very impressive, but it means precisely nothing, unless by any chance it means spinal arthritis! There are quite a number of these little joints, but there is nothing particularly complex about them and they behave very much like any other joints. The mystery deepens when we come to Prof. Platt's last and apparently most important group of cases—namely, "pseudo-sciatica—fibrositis of the fascial, ligamentous, and muscle masses in the lumbar region, buttocks, and thighs." There is not a shred of evidence that any of these conditions is directly concerned in the causation of sciatica. A patient either has sciatica or he has not. Pseudo-sciatica may well rank with P.U.O., D.A.H., and other well-known subterfuges in the absence of a correct diagnosis.

Prof. Platt is right in saying that I have never claimed the "vertebral arthritis theory" as my own creation, but he is wrong in saying that it has my unqualified support, because I have always recognized that there are other causes of sciatica. However, I do know that the majority of my patients with sciatica have symptoms and signs of spinal arthritis and that they respond to the appropriate treatment. What are the majority of Prof. Platt's sciatica patients suffering from?—I am, etc..

London, W.1.

A. S. BLUNDELL BANKART.

SIR.—While I am in agreement with much of Mr. Harry Platt's reasoned and in many ways skilful defence of the orthopaedic surgeon's point of view with regard to sciatica—particularly do I like his five clinical groups—I take exception to what he says about manipulation. Many years before Goldthwait and Osgood of Boston ever mentioned sacro-iliac joint strain in connexion with sciatica, osteopaths had pointed out that many cases of sciatica were due to postural defects or to positional "lesions"—strains, if you prefer it—of one or more joints in the pelvis and lumbar region.

Why orthopaedic surgeons experience "far too many failures" after manipulation is due largely to their faulty technique. In the vast majority of cases a forced manipulation, with the patient under an anaesthetic, is given by an orthopaedic surgeon, and the patient is then handed over to the care of a masseuse for subsequent treatment. Orthopaedic surgeons learn their manipulative technique on anaesthetized patients, when the whole question of active joint strain and protective spasm of muscles and ligaments is eliminated by anaesthetic. Little or no effort is made really to understand the mechanical problem of each individual patient and each particular joint is mainly or primarily on strain. I have treated many hundreds of cases of sciatica by osteopathic manipulation with a very high percentage of pleasing results, both with and without anaesthesia. Practically never, however, have I succeeded in entirely curing any case of sciatica after one manipulation under anaesthesia. In the cases where I have resorted to anaesthesia it has always been necessary to continue manipulation, without an anaesthetic, for a varying period of time afterwards, until the tension in the joint and the protective spasm of the muscles and ligaments are entirely eliminated, and the patient's faulty posture is corrected; this necessary result cannot be attained by one manipulation under anaesthesia. I have only resorted to anaesthetics in cases where there has been some psychological necessity on account of the fear of pain, the extreme protective spasm of the lumbar muscles making it entirely impossible to obtain any movement whatever without an anaesthetic, or possibly in some cases on account of the possible saving of time.

I seriously put forward this criticism of orthopaedic surgeons' technique as the real reason why they get such a high percentage of failures from manipulation, and nowadays are so prone to

remove an intervertebral disk instead, and I suggest that if they elaborated their manipulative technique along the lines I have indicated they would get better results and find less necessity for resorting to serious surgical intervention. Perhaps they prefer surgery.—I am, etc.,

London, W.1.

GEORGE MACDONALD.

### Treatment of Sciatica

SIR.—Sir Arthur Hurst raises some interesting points in the *Journal* of Dec. 18 (p. 773). In the course of over 15 years' experience in an electrotherapeutic department a large number of these cases have passed through my hands. During my first few years I found that very variable results were obtained in these cases, whereas a much quicker and more consistent response to treatment was obtained in cases of brachial neuritis. This called for careful thought, and I came to the conclusion that the essential features responsible for the good results in the latter group were: (1) The arm is kept in a sling until the pain has diminished considerably. (2) The diathermy or short-wave current is passed through the entire upper extremities, and including particularly the cervical plexus in its path. On a number of occasions when patients have not been responding well I have found that the assistant has not placed the upper pad (or condenser) sufficiently high to include the cervical plexus in the path of the current; when this has been corrected all these cases improved rapidly. This convinced me that the origin of the condition was situated in the region of the roots of the nerves.

On attempting to apply these principles to cases of sciatica certain difficulties were encountered. It is not possible "to put a leg in a sling," and during the acute stage I found that the exertion of moving from a chair to the treatment room more than counteracted the beneficial effect of any form of physiotherapy. For this reason I advise complete rest in bed during this stage. Until 1934 these cases were treated by diathermy, and particularly in thick subjects it was not possible to obtain an effective concentration of the current through the lumbar plexus. With the introduction of short-wave therapy and the adoption of the Schliephake three-condenser technique it became possible to include the entire course of the sciatic nerve in the tract irradiated, and a marked improvement in our results was obtained.

Sir Arthur states: "The few patients who do not get well after a month of complete rest in bed are among those who give a history and show physical signs of root pressure. A further period of complete rest may still lead to recovery, but if there has been little or no improvement they should be referred without further delay to a neurosurgeon, who will cure them by removal of the herniated intervertebral disk." The great majority of our cases do not come to the department until they have had several weeks' rest in bed and are still complaining of considerable pain and disability. At this stage short-wave therapy is given daily for two weeks, and at the end of this period a marked improvement is seen in their condition; treatment is usually continued three times a week for a further two weeks if necessary, but a number of cases are completely cured in two weeks. As soon as the acute phase has passed, massage and exercises are given. If it is possible to admit the patient to hospital, treatment may be started at an earlier stage.

These observations support Sir Arthur's view that the pain frequently arises in the roots of the sciatic nerve, and suggest strongly that neurosurgical procedures are not indicated in the great majority of these cases until there has been a period of rest followed by a course of short-wave therapy.—I am, etc.,

Jpswlch.

C. H. C. DALTON.

### Shock Treatment of Mental Disorder

SIR.—Dr. Winnicott's provocative letter will probably bring many replies from psychiatrists who have obtained good and lasting results from shock therapy. It is now possible to employ a criterion on results obtained in those cases remaining well some years following discharge from mental hospitals. In spite of some conflicting statements these results appear to justify the validity of individual experiences.

After four years' experience of all modern methods of shock therapy employed in mental hospitals, I am convinced of its value in carefully selected cases. I might add that

these four years follow twenty years of psycho-analytical work. The value of insulin shock in schizophrenia appears to me to be largely due to the greater facilities for employing psychotherapy during the actual treatment. This led me to favour the intramuscular injection of triazol, azoman, etc. The latter technique allows an interval for psychotherapy before the convulsions. The more or less acute anxiety occurring during this period is generally of a regressive type, and if desired can be used as a method of forcing a transference situation. The good results following electric shock therapy employed in involuntional melancholia speak for themselves.

I believe that shock therapy combined with psychotherapy offers a new and promising approach in the treatment of the psychoses, and until a less drastic approach is discovered its condemnation is unjustifiable.—I am, etc.,

Dartford.

ROBERT M. RIGGALL.

SIR,—Although I am a psychiatrist and psychotherapist who does not personally give electric convulsive therapy, I cannot let Dr. Winnicott's letter on this subject pass unchallenged.

First, I should like to know what evidence Dr. Winnicott has for saying that a patient who consents to this treatment is doing it out of an impulse akin to a suicidal one. Having seen many patients who have consented to, or even asked for, this treatment I myself can produce no similar evidence. Secondly, it is surely fanciful to suggest that one orders it as a punishment to the patient for not getting well. On the contrary, the physician who insists that the patient shall get well by the treatment which he himself is able to administer or not at all is actually punishing the patient much more severely!

Psychotherapy is as yet far too immature a science for its exponents to say dogmatically that it is the answer to every psychiatric illness. One has seen far too many cases going on for month after month, and even year after year, with psychological treatment which is doing no good whatever. To find a treatment that in suitable cases offers speedy and sure help to these unfortunate people is one of the greatest advances which medicine has made, and it would be a thousand pities if any part of the profession was prejudiced against it, either on the score that it is delaying a knowledge of psychopathology or on the score of dogmatic and unproved psychological assertions.

Dr. Winnicott does not seem clear that the choice of treatment in psychiatric illness must, as in other branches of medicine, depend upon diagnosis, or that there are certain forms of illness—such as anxiety neurosis—for which, other things being equal, psychotherapy is the method of choice; and others—notably involuntional depression—where psychotherapy is useless and electric convulsive therapy is 80% effective. If he has not read Sargant's and Sands's work on the latter I am sure he would find it of interest. It is a patent misconception to suppose either that the two methods of treatment are interchangeable or that the one is a "short cut" to the other.

Finally, is it ethical to refuse any patient the appropriate treatment for his illness because to do so might advance our knowledge of pathology?—I am, etc.,

London, W.1.

MARION GREAVES.

### Teaching of Anaesthetics

SIR,—I am sure all teaching anaesthetists will agree most heartily with the points raised by Dr. K. G. Lloyd-Williams (Dec. 25, p. 827) with reference to the instruction of medical students. For many years newly qualified practitioners have complained with some bitterness that the methods of anaesthetic administration employed in hospital practice are too complicated for use outside. Now that specialist anaesthetists are in short supply the position has become acute, and the ignorance displayed by the average house-surgeon regarding the elementary principles of anaesthesia is truly amazing—not to say terrifying! In the various E.M.S. hospitals which have sprung up all over the country many anaesthetics have to be administered by residents (and others) who have had no special training in anaesthesia, and their well-meant but hair-raising attempts to produce scientific asphyxia are a continual source of worry to the visiting surgeons.

No useful purpose will be served by blaming the honorary anaesthetists at the teaching hospitals, most of whom do their best for patient, surgeon, and student, often under very trying conditions. It has long become evident, however, that modern anaesthesia is a highly specialized subject which cannot possibly be taught to medical students in the short time available. Furthermore, as Dr. Lloyd-Williams points out, the main operating theatre, with its list of gastrectomies, thyroids, and gall-bladders (not to mention exacting and temperamental surgeons), is no place for the beginner in anaesthesia, and the sooner this is realized by the academic and hospital authorities the sooner will a satisfactory solution be arrived at.

The present system, whereby the student goes the round of various operating theatres, picking up indiscriminate information as he goes along, is confusing and unsatisfactory for many reasons. For one thing, not all honorary anaesthetists are good teachers. Would it not be far more satisfactory for each hospital or medical school to appoint an anaesthetic tutor, who would be responsible for teaching students the cardinal principles of anaesthesia in the same way that the surgical registrar instructs the dressers in the elementary principles of surgical asepsis, case-taking, and the like? Under his supervision anaesthetic clerks would spend the first part of their course (say, two weeks) learning: (1) clinical signs and symptoms of the various stages of anaesthesia; (2) how to maintain a free airway; (3) the recognition of normal and abnormal respiration; and (4) how to administer a simple routine "open" anaesthetic. With the co-operation of the R.S.O. special lists could be arranged of relatively minor operations, so that each student would gain practical experience of the right kind. The third week could be devoted to giving short anaesthetics with nitrous oxide or intravenous drugs in the casualty, dental, and maternity departments, while the fourth and final week might be used for purposes of revision. At the end of the course each student should undergo a practical test by the senior honorary anaesthetist or lecturer, and any student falling below a certain standard would be compelled to take a further two-weeks course.

Where do the honorary anaesthetists come into the foregoing scheme? In my opinion the most useful plan would be for each honorary to give one demonstration in some special method of anaesthesia at the end of the ordinary course—e.g., basal anaesthesia with nitrous oxide and oxygen for toxic thyroid cases, cyclopropane-oxygen with carbon dioxide absorption and "controlled" respiration for thoracic surgery, spinal and regional analgesia, and so on. This would enable the student to appreciate the advantages of modern technique without being expected to take any active part in it. If any particular student wished to learn more about modern methods he would naturally take a postgraduate course in anaesthesia after qualifying.

The appointment of an anaesthetic tutor would lead to all sorts of advantageous possibilities from the point of view of the hospital. As in the case of resident surgical officers or registrars he should be a young man at the beginning of his professional career, preferably with not less than twelve months' experience as resident anaesthetist. In addition to teaching students he would be responsible for training and supervising the residents, and might also undertake difficult emergencies or assist in the special departments. Last, but decidedly not least, he could be responsible for keeping the hospital records up to date.—I am, etc.,

Newcastle-upon-Tyne.

PHILIP AYRE.

### Cerebral Malaria

SIR,—I beg space to add a postscript to Surg. Lieut. I. B. Sneddon's article (Dec. 25, p. 814). I write as one with fourteen years' experience of tropical work in Malaya and two in West Africa. In Malaya my partners and I were responsible for the health of some 80,000 Asiatic workers on rubber estates and tin mines, as well as a great number of Europeans. Cerebral malaria was relatively common, the Malayan strain of the subtropical parasite being, in my experience, infinitely more virulent in this respect than the West African. We lost very few cases indeed—not one being a European—in all those years, and the reason was, I am sure,

that we did not spare the quinine. Adult cases were given two, and sometimes three, intramuscular injections of 15 gr. of quinine daily. These were given into the upper and outer quadrant of the buttock. I have never seen any untoward effects from this dosage, nor have I ever had a quinine abscess of the buttock, even after repeated injections, as a sequela. Usually two or three injections suffice, but if vomiting or coma persists the injections have to be continued until these signs disappear.

My top score for any one case was the rather amazing number of 14 injections of 15 gr. each, spread over seven days, and the patient, one of my Indian assistant surgeons, made an excellent recovery, and was extraordinarily grateful for the cure, particularly as he himself had lost a case of cerebral malaria—his European estate manager—two months previously. This manager had refused to take quinine in sufficient dosage, either by mouth or by injection, as he averred that he only had a "headache" and he saw no reason why the assistant surgeon should fill him up with quinine when aspirin was the thing for a headache. He became comatose and died on his 90-mile journey down from the Ulu to hospital.

The moral is—and here I agree most heartily with Dr. Minett of the Gold Coast, who wrote in the same strain a few weeks ago—that one must take extremely energetic steps with any case of malaria, particularly subtertian, that suffers from a really severe headache or that appears to be semi- or fully comatose.

In contradiction to Lieut. Sneddon's statement that one usually finds a large number of parasites in the circulating blood in comatose cases, my experience has been the opposite, and some of my worst cases have shown only one or two parasites in a complete thin film. On the other hand, I have seen parasites in one field so numerous as to be almost uncountable, and yet the patient never showed any signs of the cerebral condition.

Give your quinine in ample doses—30 to 45 gr. daily—by injection, whether intravenously or intramuscularly I care not; though personally I found it more convenient to give by the intramuscular route. The boggy of quinine abscesses need not arise if one is certain of the sterility of syringe and quinine solution, and if one ensures that the injection is intramuscular and not merely into the subcutaneous fat of the buttock. I have always used ampoules containing 15 gr. of quinine bishydrochloride in 2 c.cm. of water, and, it is almost unnecessary to state, boiled syringe and needle before each injection.

If the many doctors, both at home and abroad, who are coming up against malaria for the first time and who regard it as a rarity, would stop "dabbling with 7½ gr. of quinine at a time and then waiting to see what the effect is," and give instead at least 30 gr. daily, we would have to record far fewer of these sad cases of fatal malaria—sad because useful lives are thrown away that might have been saved.—I am, etc.,

I. G. CAMERON,  
Major, R.A.M.C.  
Medical Specialist (Tropical).

SIR,—In 1937 I had a rather similar case of cerebral malaria, blood, etc., in the urine, to that reported by Dr. Sneddon (25, p. 814). I was a resident in Manchester Royal Infirmary at the time. The patient was the soldier son of my wife's landlady. He had just come home on leave from Palestine, and was apparently in the pink of condition. (It was the time of the intensified disturbances in Palestine.) I had been introduced to the boy on his arrival home, and when I heard that he was dangerously ill with acute nephritis and delirium I was puzzled. I presumed on the family doctor's courtesy and took a blood slide, for it occurred to me that the patient might conceivably be the victim of malignant malaria.

It was fortunate in this instance that I had overstepped my position, for the slide (which I still have) showed numerous crescents (both male and female) of malignant malaria—i.e., *Plasmodium falciparum*. After informing his doctor it was arranged that the patient should be admitted to Manchester Royal Infirmary, where, if memory is correct, he was treated with quinine and plasmoquin. After a sharp illness the man subsequently recovered and was discharged some weeks later.—I am, etc.,

Conon Bridge.

KENNETH I. E. MACLEOD.

## Population Problems of India

SIR.—It is surprising to see put forward in all seriousness in a scientific journal the dismal and long-discredited theories of the reactionary parson Malthus, which have long been laughed at by scientists and economists of all schools. Prof. Blacklock does not suggest in his article on the population problem of India (Dec. 25, p. 805) that the present terrible famine in India is due to over-population, but there is as much justification in arguing this as in visualizing future famines in India due to over-population. "Where is the Indian Malthus who will inveigh against the devastating torrent of Indian children?" asks a leading economist.<sup>1</sup> And another,<sup>2</sup> "India seems to illustrate the theories of Malthus." Let us examine the arguments of this new "Indian Malthus."

He puts forward assumptions based on the presumed application of the principles of the Atlantic Charter to India, but have we not already been informed by Mr. Churchill that the Atlantic Charter does not apply to India? Some 247 persons per square mile seems a great density of population until we compare it with that of England and Wales, which in 1931 was 685 persons per square mile. Further, while India's population between 1881 and 1931 increased by almost 40%, that of England and Wales increased in the same period by almost 60%—that is, by half as much again.

Considering the problem of food production, the solving of which is the key to India's future, we find that in four years in Great Britain the amount of food produced was doubled (1939-43)—that is, we now produce two-thirds of our food instead of one-third, as we did before the war. Many agricultural experts assert that we are quite capable of producing all our food requirements in Britain. Let us now consider India. The following quotation<sup>3</sup> refers to Bengal, the most densely populated part of India: "... Of the total area cultivable only 67% is now actually under cultivation. If the total cultivable area were brought under cultivation, and if improved methods of cultivation yielding an increase of 30% over the present yield were adopted, it is clear from a simple rule-of-three calculation that Bengal could support at its present standard of living a population very nearly twice as large as that recorded in 1931." One can add that if it is humanly possible to multiply food production by three in Britain, it cannot be impossible in Bengal.

Instead of homilies about restraint and birth-control I would suggest that British medical men interested in the future of India should advocate the application of the Atlantic Charter principles to India, which would give her the right to self-government—a necessary preliminary to improvement in the food situation or anything else.—I am, etc.,

Nelson, Lancs.

T. D. CULBERT.

SIR,—India's growing population has been blamed by the spokesmen of the British Government for the present famine and also for the poverty, ill-health, and low standard of life of the Indian masses. Prof. D. B. Blacklock's article is also written in the same vein. He may have meant well, but his references to the Atlantic Charter make your Indian readers and many others very suspicious.

India is not the only country with a rapidly increasing population. In fact she is far behind the big European countries in this respect, as the following figures show:

## Increase in Population in 50 Years

Russia	..	..	..	..	..	73.9%
Holland	..	..	..	..	..	62.0%
Germany	..	..	..	..	..	59.0%
England	..	..	..	..	..	58.0%
India	..	..	..	..	..	18.9%

These figures show that the population problem should be considered more serious in this country than in India, especially when everyone knows that even with the most modern methods England cannot feed more than half of her population. Yet people here are being advised and encouraged to have more babies. Why? Because it is not only the land that counts but also the industrial production. Prof. Blacklock presupposes

that India will remain mainly an agricultural country, perhaps because the policy of British capitalists has been to keep India only a dumping ground for their goods. But India can be made a great industrial country.

The Indian problem cannot be solved by limiting the population alone, but by better education, better health and social services, modern methods of agriculture, and industrial development. Who can bring about these changes? As Prof. Blacklock rightly points out, this is the responsibility of Indians themselves. But have the Indians got sufficient power to bring about these changes? The answer is in a big NO. Only an independent Indian Government will have the power, the courage, and the resources necessary for such changes.

Prof. Blacklock tells us that out of 6,000 civilian doctors in India only 200 are British. But he does not tell us that these 200 have the real power. They control all the highly paid key posts and frame the policy. They derive their instructions from Whitehall. Only one example will prove it. Recently a Commission was appointed to report on reforms in the I.M.S. All its members were British, so was Mr. Souttar, its chairman. And India has dozens of medical men as capable as any member of the Commission.—I am, etc.

Birmingham

D. R. PREM.

### Hypoglycaemia

SIR.—Recent correspondence on this subject has indicated that spontaneous hypoglycaemia occurs rarely, and that it is suspected too frequently, and is "overdone as an explanation for minor indispositions." It has also been pointed out that hypoglycaemia may be a concomitant of a number of disorders. It may be that the swing of the pendulum has gone too far, and a corrective to over-zealousness was well warranted. It is, however, not so many years ago since endogenous hypoglycaemia was entirely unsuspected—at least by the majority of physicians—as a cause of convulsions, or loss of consciousness, or peculiarities of behaviour; and publications of such cases in recent years still show that the diagnosis has often been missed by one or more physicians.

Although it is true that the diagnosis of endogenous hypoglycaemia is often invoked without sound evidence to explain minor indispositions, it is also true that fatal hypoglycaemic coma may occur in the course of three major endocrine disorders—namely, Addison's disease, Simmonds's cachexia (anterior pituitary deficiency), and adenoma or carcinoma of the islets of Langerhans in the pancreas. Addison's disease should, of course, be diagnosed on clinical evidence, and often is. Nevertheless, in the course of the disease a severe or fatal endogenous hypoglycaemic attack may occur, and its true nature remain unrecognized. This complication is more likely to occur when desoxycorticosterone therapy is used in preference to cortical extracts, which also contain the corticosterone carbohydrate regulating factor. (Nevertheless desoxycorticosterone is completely adequate therapy with some patients.) Simmonds's cachexia may be atypical in its manifestations, especially when following parturition, and the original disorder, as well as the incidental hypoglycaemia, may remain undetected. A pancreatic islet tumour may well be unsuspected because of its rarity. If the diagnosis of Addison's or Simmonds's disease is made, adrenal cortical extracts will tend to prevent hypoglycaemic attacks; and the latter will be more specifically guarded against when the pure corticosterone factor becomes available commercially. If a pancreatic islet tumour is diagnosed, laparotomy and removal are indicated.

These few comments in no way detract from the validity and value of the observations made by previous correspondents on this subject, but serve, I venture to hope, to stress another aspect which is not unimportant.—I am, etc.,

London, W.I.

S. L. SIMPSON.

### Obstetric "Shock" or Haemorrhage?

SIR.—We have read with interest the short article on blood transfusion in "obstetric shock" (Dec. 18, p. 781), and the subsequent correspondence. From this four points emerge for discussion. First, the use of the term "obstetric shock"; secondly, the beneficial effect of transfusion in conditions so described; thirdly, the complete absence of haemoglobin estimations throughout the whole series of cases quoted; and, fourthly, the persistent statement that haemorrhage had not been excessive.

We have had a very extensive experience of transfusion in such cases, and the obstetrician has always made the diagnosis of "obstetric shock"—and amplified it by the statement that haemorrhage had not been excessive. Haemoglobin estimations have always been made by us before and after treatment, and treatment has always consisted of much more massive transfusion than any of your correspondents have described. The haemoglobin percentage may or may not have been below normal before transfusion was started, but it has never been above normal during the three days after transfusion, and has frequently been as low as 70%. The minimum volume transfused has been three pints of citrated blood, and the majority of such patients have received five to seven pints of blood. Before transfusion the pulse rate has been raised, 110 to 140 per minute, but has fallen as transfusion proceeded. Where retained placenta has been the cause of the so-called "shock," removal of this organ has been successfully accomplished after transfusion, no matter how severely ill the patient may have been, and the conclusions that we have arrived at are either that severe anaemia is the precursor of the retained placenta and obstetric shock or that severe haemorrhage has always occurred in our cases of "obstetric shock," haemorrhage being much the more likely diagnosis.

We cannot imagine how any patient can accommodate within the circulation five pints of blood, often transfused at an extremely rapid rate—two pints during the first quarter of an hour and a further two pints in the next half-hour—if there has not been a corresponding loss of blood volume preceding the transfusion. If the space available for this transfused fluid is due to dilatation of the vascular bed rather than loss of fluid, then transfusion of whole blood should raise the haemoglobin to a level of 150% or thereabouts when the patient has recovered. We firmly believe that the use of the term "obstetric shock" should be abandoned; all cases that we have seen have been due to blood loss as judged by comparison of the haemoglobin levels before and after transfusion of whole blood, and this in spite of the fact that obstetricians generally say that blood loss has not been excessive. In the great majority of cases the obstetrician has not been present throughout the course of labour to see for himself what has taken place, but it is easy to convince oneself of the correctness of our contention if haemoglobin estimations are made in all such cases before and after transfusion.

Only when the term "obstetric shock" is abandoned in favour of the term "obstetric haemorrhage" will the treatment necessary in these cases be recognized and applied. In support of this contention we would quote one case of complete inversion of the uterus. After replacing the uterus this patient received fourteen pints of citrated blood, and within thirty-six hours had a normal pulse rate, 100% haemoglobin, and thereafter a normal puerperium.—We are, etc.,

### Treatment of Gonorrhoea in the Female

SIR.—The excellent summary of the modern treatment of gonorrhoea in the female by Brig. T. E. Osmond (Jan. 8, p. 51) has stimulated me to comment upon the local activity he recommends in labour and the pyrexial puerperium.

Instead of his recommendation that when labour starts an endeavour should be made to cleanse the birth canal, I would advocate that only the vulva be kept as clean as possible, and that the aim should be to carry out no vaginal or rectal examination throughout labour, or even late in pregnancy. In managing the labour the abnormalities should be detected by other means than by vaginal or rectal examination. When operative intervention is judged to be necessary the cleaning of the vagina and performance of the internal examination are best made under the anaesthesia.

In the puerperium in these contaminated cases no condition except vaginal haemorrhage, severe or repeated, should provoke local intervention, even of as gentle a nature as the passage of an intra-uterine catheter and the instillation of glycerol as recommended by Brig. Osmond. The efficiency of this policy of intervening even less than in non-veneral cases has been confirmed over many years.—I am, etc.,

London, W.I.

AMY M. FLEMING.

## Scabies

SIR,—I should like to implement some of Dr. Mellanby's observations in his letter (Dec. 18, p. 795). First, regarding one-application treatment. The figures for the year 1943 are not yet complete, but a rough survey indicates that relapses are very infrequent—in fact, well below 1%. The following investigation carried out by the charge orderly at the treatment centre proves the efficacy of the one-treatment method. Eighty persons were chosen who on the first examination had live mites on the hands and/or wrists; 40 were treated with the lanette wax benzyl benzoate emulsion 20% and 40 with triethanolamine stearic acid B.B. preparation, also 20% B.B. A total of 974 mites were taken from the 80 patients following treatment—i.e., average of approximately 12 mites per case; all the mites on test were found to be dead. The times between treatment and the test of the mite being dead varied between a quarter to half an hour. In no case did more than half an hour elapse between treatment and test.

Another investigation carried out showed that home treatment is, generally speaking, a failure. It is known that sulphur ointment, benzyl benzoate, and demethyl-diphenylene disulphide (D.D.D.) are all efficient sarcoptocides. Patients are questioned as to any treatment just before attendance at the centre; if any medicament other than those mentioned had been used the case was ignored. The patient's hands and wrists were carefully examined for mites; if no mite was found the case was ignored; if one live mite was found it was obvious that treatment had not been successful. A total of 347 patients had used one or more of the three above-mentioned medicaments; in 15 cases only were all dead mites found—a success rate of 4.31%.

With regard to reinfestation from fomites, I consider this plays a minor part in the spread, and from a local authority's point of view the disinfection of the fomites would divert man-power and money for very minor results. For example, in the areas served by the Poolsbrook Treatment Centre, if disinfection of clothing, bedding, etc., were carried out it would mean the employment of an extra driver and van doing a mileage of 30,000 annually. In addition an extra man would be required to attend to the disinfectant, etc.—a bill of roughly £490 per annum in wages and £750 in running costs of a van. This does not include cost of fuel and "wear and tear" of the disinfectant. This sum would represent over a penny rate for the authorities concerned for a reduction of 1 to 2% at the most in the reinfestation due to fomites.

To combat scabies successfully there should be a really well-trained and skilled staff at the treatment centre or cleansing station; and success of the treatment will be limited unless whole families attend. Our figures show that, irrespective of the size of the family, if scabies gains an entrance to the household 80% of the members are infected. In fact the household group is not a sufficiently large unit to aim at for attention; in many instances the "yard," "court," or block of houses should be the unit for examination.—I am, etc.,

JOHN R. GRAHAM,  
Medical Officer of Health, Chesterfield.

## Infective Hepatitis

SIR,—Dr. I. Gordon's excellent and comprehensive study of epidemic non-spirochaetal jaundice (Dec. 25, p. 807) raises again the problem of the nature of jaundice. The main difficulty is to decide whether we are to consider the ordinary case of jaundice, familiar to every practitioner, as a sporadic form of infective hepatitis or as a different type of jaundice with different aetiology.

Since Eppinger (*Die hepato-lienalen Erkrankungen*, Vienna, 1920) discovered for the first time inflammatory and degenerative changes in the liver of a young girl who committed suicide while suffering from "simple" jaundice, the view that simple "catarrhal" jaundice was due to a hepatitis has been generally accepted abroad, and Virchow's conception of jaundice as being caused by an obstruction due to a swelling of Vater's papilla or to the formation of a mucous plug in the common bile duct was more or less abandoned. Impaired galactose tolerance, which could frequently be demonstrated in such cases, favoured the assumption of a primary lesion of the liver parenchyma.

Hurst and Simpson (*Guy's Hosp. Rep.*, 1934, 84, 173), however, still maintained that true "catarrhal" jaundice was caused by an obstruction of the common bile duct, and could be differentiated clinically from jaundice produced by a "primary hepatic necrosis," a condition obviously identical with what is now commonly called hepatitis. Findlay (*J. R.A.M.C.*, 1940, 74, 72), though recognizing two different types, believes that differentiation on clinical grounds is not possible, and Dr. Gordon's series of cases proves that the clinical features of epidemic hepatitis may be indistinguishable from those of any other type of jaundice.

Although there is conclusive evidence of hepatitis in cases of so-called catarrhal jaundice, and though signs and symptoms of the latter condition and of infective hepatitis can be identical, it seems to be premature to regard every case of jaundice as a case of epidemic infective hepatitis before the causative agent has been discovered and can be demonstrated in every case of icterus. On the other hand, there is anatomical pathological evidence for the assumption that more than one factor plays a part in causing jaundice. A differentiation of cases of icterus can be made with the Takata reaction, especially by the modification which I described in 1936 (*Guy's Hosp. Rep.*, 86, 166) and which has been used successfully by many authors (cf. Ucko, *J. Lab. clin. Med.*, 1942, 28, 17). This very simple test gives negative results in the majority of cases of "simple" jaundice, and more or less strongly positive results in some cases without distinguishable clinical features. As the test indicates a disturbance of the protein metabolism in relation to the liver function, it can be concluded that this function of the liver is disturbed only in a certain number of cases of jaundice. The results of the test point therefore to the existence either of two different types of jaundice or of cases with and without impairment of the protein-regulating function of the liver. If employed more regularly, and possibly combined with other function tests and with biopsy experiments, it is likely to throw more light on the aetiology and the nature of icterus simplex.—I am, etc.,

London, W.1.

H. UCKO.

## Transportation of Fractured Femur

SIR,—The article by Lieut.-Col. Wood Power in the *Journal* of Oct. 23, 1943, was of great interest to all concerned with surgery in the forward area. He described and criticized a type of "Tobruk" plaster for fractured femur that has been largely superseded by a variation which doubtless my surgical colleagues will describe when further experience has enabled them correctly to assess its value. It has been used by many surgeons for the last 18 months, but not under the rigorous conditions described by Lieut.-Col. Wood Power. He had to rely on single-track railways for the evacuation of his casualties. Whether this improved "Tobruk" would have been successful but for that magnificent double-track railway that linked the Wadi Zemzen with Benghazi, or the all-electric line between El Hamma and Tripoli, is open to doubt.—I am, etc.,

R. BINNING,  
Major, R.A.M.C.

## Urine and Blood Urea under Sulphonamides

SIR,—I wish to record this case in order to emphasize the importance of quantitative analysis of the urine and blood urea estimation when sulphonamide drugs are given to patients on low diet.

A man aged 42 was admitted to the Royal Gwent Hospital suffering from a prepyloric ulcer of 20 years' standing, and for which he had undergone several courses of medical treatment. On Nov. 25, 1943, I performed a partial gastrectomy. He received two pints of plasma on his return to the ward and his condition appeared to be satisfactory. On Nov. 29 he complained of pain in the right side of his chest; his temperature was 101° F., and his leucocyte count was 13,000. An early pneumonia was suspected, and he was given four tablets of sulphathiazole, followed by two tablets every four hours with 1 drachm of sod. bicarb. His temperature returned to normal and there was no vomiting, but his general condition deteriorated. His fluid intake and urinary output were said to be satisfactory but were not measured.

On Dec. 2—i.e., seven days after the operation—I was told that his urinary output had ceased. He looked very ill, and his blood urea was found to be 312 mg. per 100 c.cm. He had received 29 tablets—i.e., 14½ g. of sulphathiazole. This was stopped immediately,

and he was given one pint of sod. sulph. 4.25% and two pints of 5% dextrose saline intravenously. This was followed by two pints of plasma and one pint of blood. During the course of the next few days his urinary output and blood urea returned to normal. He recovered, and has since been discharged from hospital.

In my opinion the kidney dysfunction was due to the administration of sulphathiazole when the patient was on low diet, and would probably have been avoided by the administration of more intravenous saline, etc.—I am, etc.,

Newport, Mon

J. T. RICE EDWARDS.

### Examining the Neurotic

SIR,—I trust these comments on the letter from Major Stungo and Captain Charlton (Dec. 25, p. 830), referring to the paper by Stephenson and Cameron, may be of interest.

It is important, particularly in dealing with large numbers of neurotics in a more or less summary fashion, to avoid being doctrinaire, and, with an open mind to the circumstances of each patient, to bring the force of all available facilities to bear on the condition. Physical investigation is one of the least time-consuming and most commonly available of psychotherapeutic facilities. Many patients have ideas about medical investigation and treatment, and that is one of the circumstances to be borne in mind. The dull and backward, for example, if they have not arrived at the stage of hopeless acceptance of symptoms, may have the desire for investigations, commonly attributed to pre-war Harley Street clientele, and with such a patient—who has, shall we say, had a head injury a year previously, with subsequent headaches, and who is anxious to have some investigations done—the most immediately effective measure may be to say to him, "All right, we will have your skull x-rayed in the morning." The would-be enlightened, on the other hand, may consider that psycho-analysis is what he stands in need of, and if we can say to him, "All right, we will have you psycho-analysed in the morning," I am sure it would be a great help. Avoidance of special physical investigations may be interpreted by one patient as a sign of confidence on the part of the psychiatrist, and by another as a continuation of the neglect to which he considers he has been for too long subjected. To undertake a physical investigation may be an indication that the psychiatrist is prepared to accommodate to the patient's attitude, and this reason I regard both as more effective and more scientific than the orthodox reason of physical examinations and investigations being done for the sake of impressing the patient.

In general, how a thing is done or not done may be more important to the neurotic than what is done or is not done, and there is room for differing practices in this field. It may be that the evils of over-investigations are on the wane and may not require much further emphasis. We are not so rich in effective therapeutic measures that we can ignore help from any quarter. The remark that "neurotic dyspepsia should be identified by means of positive psychiatric criteria and not by the negative findings of gastric investigations" is, I am sure, commonplace, but, in addition to the therapeutic value, physical investigations may also be helpful in assessing the degree of somatic dysfunction present and diagnosing or excluding conditions which commonly keep company with anxiety states but are best treated by other than psychological means, should there be sufficient indications that such a condition may be present.

With regard to dyspepsia, the prevalent assumption among medical men appears to be that there are many cases radiologically not showing ulcers which give indications of both a morbid mental attitude to alimentary functions and a disorder of these functions themselves, and if a psychiatrist is fortunate enough to have the help of a physician with experience in the diagnosis and perhaps in the treatment of these conditions along re-educative lines by dietetic means he should certainly take advantage of it, and whether the usual procedure of the patient being seen first by a physician is followed or not would seem to be a matter of administrative convenience and personal preference.

The report by Stephenson and Cameron of the typical course of anxiety states occurring in Service conditions, with the clear account of the three stages that these patients may pass through, is surely most valuable, and to describe the changing course of a neurotic illness is a contribution of more

special interest than would be indicated in the term "the reiteration of symptoms alone." I have no doubt that Stephenson and Cameron fully appreciate that if they were able, by choosing necessarily smaller groups, to give an account of very similar findings in the course of the illness, with personality findings showing striking similarities in the patients within each group, that would be still better, but the two factors which make that very difficult are the time-consuming nature of personality investigations, with the very unusual experience and skill required, and the great diversity of individual personalities. Even if patients are selected in whom similarities in personality make-up are to be expected—such as cases of conversion hysteria or effort syndrome—a psychiatrist, albeit gifted with some imagination, may search long enough before he finds two patients with strikingly similar personalities; and if you collect half a dozen that give that impression, the likelihood is that three or four may stand the test of expert investigation and the others be a bit weak in respect of their adherence to the standard personality of the group. A further difficulty is that people of very different personality make-up may react to stress in a superficially similar manner. I appreciate, however, that in patients of similar symptomatology some traits will be revealed with significant frequency on a personality assessment. I agree that the structure of the personality will be the diagnostic criterion of the future, and do not wish to fall into the same error as Stungo and Charlton in being over-critical of contributions of one sort in emphasizing the importance of an approach of complementary value.

One further point. Stungo and Charlton ask us "to correlate personality types with the relevant anxiety reaction," and in the course of their letter they give a result of their methods of such correlation in the composite assumption that dull, highly suggestible patients are prone to exhibit neurotic dyspepsia. But this assumption implies that they have satisfied themselves on a number of difficult points—e.g., that dull patients are uncommonly suggestible; that dull patients are uncommonly prone to neurotic dyspepsia; and that it is the more suggestible of the dull who are so prone. Further, if these patients have the general attribute of high suggestibility, why should their imitation of symptoms be permanent, as is suggested?—I am, etc.,

Dudley.

W. M. MCINTYRE.

### Inhaler for Trilene Analgesia

SIR,—Dr. W. Edwards (Dec. 18, p. 795) states that a trichlorethylene-air mixture is an excellent analgesic for childbirth, and he refers to the single bottle of Marrett's apparatus which he used for this purpose as "Martha, the mechanical midwife." I must point out that this apparatus is designed for employing trilene or ether for analgesia and anaesthesia, and, as such, it should only be used by qualified practitioners. The lever on the bottle can be moved to increase the strength of vapour admitted to the patient, and the bottle must be kept upright to prevent trilene from entering the air-tube.

It was because I was satisfied that trilene-air analgesia was superior to the nitrous oxide-air technique that, with the help of Mr. A. Charles King, I designed a special inhaler. This embodied modifications which, I believe, satisfy the requirements of inhalation analgesia for childbirth and permit it to be employed with safety by a midwife. The salient features of this inhaler are: (1) the strength of the mixture cannot be increased to anaesthetic potency; (2) the liquid cannot enter the air-tube; (3) the patient administers the mixture to herself; (4) the sound made by the movement of the valves enables the person in attendance to follow the behaviour of the patient without direct supervision of the administration. An account of this inhaler with the results of its use since Nov., 1942, was published in the *Lancet* of Dec. 4, 1943.—I am, etc.,

London, N.16.

A. FREEDMAN.

### Babies in Hospital

SIR,—I shall have to take the risk of being considered likely to hold very out-of-date views if I confess to nearly 30 years of medical work among infants in children's hospitals, child welfare clinics, and private practice, but two recent medical memoranda in the *Journal* have braced me to face the risk.

The memoranda to which I wish to draw attention appeared in the *Journal* of Dec. 25, 1943, and Jan. 8, 1944, under the titles "Suppurative Mastoiditis in an Infant" and "Staphylococcal Pyopneumothorax in an Infant: Recovery." Those two articles, which are deserving of careful study by all interested in the welfare of infants, to my mind show very clearly that hospital wards can be very dangerous places in which to treat infants, while they also show that, when babies have been brought to death's door, we have in modern treatment very efficient methods for life-saving.

In both cases, from the very full notes given, it appears to me that at the time the infant was admitted to the hospital ward there was nothing in the infant's medical condition to justify this step. Could not all the necessary investigations have been carried out in a well-run out-patient department? Are not the major catastrophes described—the suppurative mastoiditis and the staphylococcal pyopneumothorax—the direct result of hospitalization? Hospital ward work in the case of young infants is carried on under crippling handicaps. Do those most closely concerned always realize that these handicaps exist? Many child welfare medical officers and health visitors, dealing as they do with very large numbers of infants of all types and thereby gaining a wide experience, have come to dread the necessity for hospitalization when the need does arise.—I am, etc.,

Nailsworth.

MARGARET DUNSTAN.

### R.M.B.F. Christmas Gifts

SIR,—It is with great pleasure that I inform you that we were able to give £3 to each of our regular beneficiaries at Christmas, which amounted to £1,566, and in addition to distribute £2 on New Year's Day as "a special surprise" to 50 of our poorest folk, the total distribution of gifts being £1,666. These figures cannot reveal the amount of happiness and good cheer brought to 522 homes, but it can surely be imagined, and the gratitude of many is very touching. Please convey to your readers my heartfelt thanks for their most generous response and support of my appeal. I am deeply grateful to all.

Many may see from this Christmas gift distribution what great and useful work the Royal Medical Benevolent Fund is doing throughout each month of the year. Will those who do not already subscribe to our general funds not forget our work in 1944?—I am, etc.,

THOS. BARLOW,

1, Balliol House, Manor Fields, Putney, S.W.15. President, R.M.B.F.

## Obituary

JOHN ALLAN CRAIGIE MACEWEN, M.B., C.M., F.R.F.P.S.

Mr. John A. C. Macewen died at 3, Woodside Crescent, Glasgow, on Jan. 12. The eldest son of the late Sir William Macewen, he was educated at the University of Glasgow. He took the B.Sc. with honours in anatomy and physiology in 1895, the M.B., C.M. with honours in 1897, and jointly gained the Brunton Memorial Prize awarded to the most distinguished graduate of the year. After a period spent abroad, studying the operative procedures and surgical technique of some of the most distinguished surgeons on the Continent, he became house-physician to Sir Thomas McCall Anderson and house-surgeon to Sir William Macewen in the Western Infirmary, Glasgow.

At the outbreak of the South African War in 1900 Mr. Macewen volunteered for service with the armed Forces, and served as civil surgeon to the British Army in South Africa. On return to this country he threw himself whole-heartedly into the teaching of surgery, which was to become the outstanding feature of his professional career. For nearly a quarter of a century he acted as university assistant—first junior and later senior—to his father, the regius professor of surgery at the University and Western Infirmary, Glasgow.

He was also dispensary surgeon to the Glasgow Royal Infirmary, assistant surgeon to the Princess Louise Hospital, Roseneath, and surgeon to the Elder Hospital, Govan.

In the war of 1914-18 Mr. Macewen, in addition to his other duties, served, with the rank of captain, R.A.M.C.(T.), as surgeon in No. 4 General Hospital, Stobhill, Glasgow; consulting and operating surgeon to several Scottish Naval hospitals; and honorary consulting surgeon to the Princess Louise Scottish Hospital for Limbless Sailors and Soldiers, Erskine—tasks which occupied every hour of the day and often much of the night. During the German advance in 1918 Mr. Macewen was transferred to France, where he worked in the military hospitals at Etaples. He used to describe the ghastly results of enemy bombing of wards full of sick and wounded, which took place, nearly every night, necessitating the resumption of work in the operating theatres as soon as the raids were over to deal with the newly created casualties. The heroism displayed by the staff on those occasions, and particularly by the nurses, left an indelible impression on his memory.

In later years Mr. Macewen became surgeon and, before he retired, senior surgeon to the Royal Infirmary. In 1924 he was appointed professor of surgery at St. Mungo's College, Glasgow—a post which he only recently relinquished on account of failing health. During a long professional life of unremitting toil he gained in full measure the confidence and affection of those shrewdest of judges—his patients, his nurses, and his students. Few surgeons can have done more operative work and fewer still have taught so many students. He was one of the most successful teachers that the Glasgow School of Surgery has ever produced. When the B.M.A. held its Annual Meeting in 1922 in Glasgow, with his father as President of the Association, Mr. Macewen held office as hon. secretary of the Section of Surgery.

WALTER M. FALLON, M.D.

Walter Martin Fallon, M.D., professor of medicine in University College, Galway, and senior physician to the Galway Central Hospital, died on Nov. 9 after an illness lasting over six months. Although he died in the early forties his perception of the difficulties of others was exceptional, and his excellent advice for their solution was always highly prized by colleagues, friends, and patients. M. G. A. L. writes:

Prof. Fallon lived a full life, crowding into his short years experience in general practice in Birmingham, study in London and on the Continent, until he finally settled in Galway as a consultant. His student days were cast in the troubled times in Ireland, but despite his many activities his course was brilliant and he enhanced his friendship with many who were foremost in the National movement and developed advanced political views which he held until he died. He entered U.C.G. in 1915 as a medical student and thenceforward scholarships and other honours fell thick upon him: he graduated B.Sc. in 1919 with first-class honours, transferred to University College, Dublin, where he obtained the M.B., B.Ch., B.A.O. in 1921, and then back to Galway, where he received the D.P.H. with first-class honours in 1922. He obtained the M.D. in 1925, and returned to his beloved Galway in 1929 as medical superintendent at the Central Hospital, and two years later was appointed to the chair of medicine in U.C.G.

Few could have more friends than he had, and he was always accessible to them, and his interests were as wide and as varied as this circle. In his profession he always kept abreast of the times—often ahead of them; he could claim to be one of the first in the British Isles to treat Addison's disease on modern principles. The best proof of all of his ability was that his professional colleagues sought his opinion on themselves, their relatives, and their other cases, and always held it in very great esteem. Consulting work, however, did not entirely satisfy him; his great interest was in the realm of preventive medicine. Almost alone he took an active part in the proper hospital treatment of pulmonary tuberculosis in Galway, and behind the scenes he was active in crystallizing public opinion in the antituberculosis drive, and left his sick-bed to attend one of the first meetings of the campaign. But these are not the activities which will enshrine his memory. As his students carried his coffin to the grave, and his colleagues in academic robes followed after, there were many more who mourned his passing. Unspoken of and unknown but to a very few, his charity had earned their sorrow. Some of the really poor realized only too well that in the passing of Prof. Fallon his surreptitious payment of the weekly rent and his shy gifts of food had also ceased for ever.

We regret to announce the death on Nov. 23, 1943, at Walton-on-Thames of Dr. JOHN MACMILLAN, D.S.O., M.C., D.P.H., medical officer of health for Woolwich, at the age of 58. Dr. MacMillan was born in Glasgow and was educated at Glasgow High School before proceeding to Glasgow University. He graduated M.B., Ch.B. in 1908 and was for a short time in general practice before obtaining an appointment in the Glasgow Fever Service, after which he took up an engagement in London with the then Metropolitan Asylums Board. Before the last war he was senior assistant medical officer and school medical officer at Willesden. He joined the R.A.M.C., and became a lieutenant-colonel and officer commanding 5th Field Ambulance in France. His services won him the M.C. and D.S.O. and the esteem of those who served under him. He was appointed M.O.H. to the Metropolitan Borough of Woolwich in June, 1919, and from that time Dr. MacMillan devoted himself to building up the health services in Woolwich. He was particularly interested in building and organizing new health centres and clinics, slum clearance and rehousing, disinfection, and health propaganda. His reputation as an expert in disinfection was appreciated in England and on the Continent. Two years before the outbreak of war he turned his attention to air-raid precautions and with characteristic thoroughness trained personnel and organized the casualty services, so that when war broke out Woolwich was prepared. As a consequence of overwork and strain his health broke down at the end of 1940, and he was forced to take a complete rest from work. He returned to duty before he was fit, and again his health broke down early in 1943. Among the many offices Dr. MacMillan held were those of chairman of the Woolwich Division, British Medical Association (1924-5), honorary secretary of the Division (since 1931), chairman of the council of the Royal Sanitary Institute (from October, 1942), and chairman of the Central Council for Health Education (1938-9). In a tribute paid to him by the leader of the Woolwich Borough Council it was said: "Medical officers of health since 1870 have played a great part in improving the health of the country, decreasing the death rate, and adding to the average expectation of life. Many of them deserve to have their names on a Roll of Honour, and on such a roll Dr. MacMillan's name would have had a very high place."

Dr. JOHN PEERE WILLIAMS-FREEMAN, J.P., who has died at Thripton, near Andover, at the age of 85, had other claims to distinction beyond those of long service as a country general practitioner of real all-round excellence and of high principles and character. Educated at University College Hospital and at Newcastle-upon-Tyne, he became M.B. of Durham University in 1885 and M.D. in 1888; in 1886 he had qualified M.R.C.S. and L.S.A. Outside his professional work he made a name of great distinction for himself as an archaeologist—at Thripton he was in a district peculiarly rich in vestiges of ancient man. An indefatigable worker and walker, there was no nook or cranny of Hampshire which he had not personally explored on foot, and few if any in Wiltshire. His magnum opus was his *Introduction to Field Archaeology*, in which he first laid down the principles of the science and then illustrated them by a conscientious review of every single ancient monument in the entire County of Southampton. This work, published more than 30 years ago, was soon recognized as a classic, and is so greatly valued that it has been for several years extremely hard to come by a copy. Here and there fuller information or further excavations led the author to modify some of his conclusions, and it has been understood for some years that he had in preparation a new and revised edition. Probably the war has interrupted publication; for the sake of a host of his friends and of his fellow archaeologists it may be hoped that his labours may see the light when the war is over. For several years after retirement he lived at Botley, in Hampshire, but returned to Thripton and died there just a few days before Christmas. Dr. Williams-Freeman was an ardent member of the B.M.A., which he joined in 1887; and country doctors owed much to him for his indefatigable work on the Rural Practitioners Subcommittee of the Insurance Acts Committee between the years 1918 and 1926.

Surg. Lieut. J. Swift Joly writes: May I crave the space of your columns to add a few words to Dr. Cuthbert Duke's excellent obituary of my father, the late J. SWIFT JOLY. To the younger generation my father will be chiefly remembered for his informal teaching in the theatre and out-patient department at St. Peter's. Visitors of all sorts, from third-year students to postgraduates and practitioners of many years' standing, were encouraged to come in at out-patient sessions whenever they wished, and they never departed without learning something new. Thousands will remember his homely illustration of litholapaxy performed on a piece of chalk in the hollow of a student's hand. To those who took a quick peep through

a cystoscope he would say, "Take it yourself, look all round, find both ureters." His patience and courtesy to the ignorant and muddle-headed type of students were exemplary. Swift Joly had a great talent for inventing and improving instruments. His cystoscope and urethroscope are universally known and used. Many will also be familiar with his bladder retractor, needle-holder, and his connexion for use with Marion's suprapubic tube. He had a very wide knowledge of physics and chemistry and won the large gold medal for chemistry at Trinity College, Dublin. In his youth he was a noted cross-country runner and a keen fisherman. In the last ten years of his life he took up mountain climbing and ascended the Dent Blanche (14,300 ft.) at the age of 61. He was an enthusiastic photographer, and his collection of Alpine photographs has been considered by his friends to be as good as that of F. S. Smythe. He was also a keen Freemason and attained the dignity of London Rank many years ago.

The tragic death of Dr. BETTY GREGORY came as a great shock to her friends, many of whom saw her apparently fit and well on Christmas Eve and heard with amazement that, as a result of a massive pontine haemorrhage she died in her sleep a few hours later. Dr. Gregory graduated M.B., Ch.B. at the University of New Zealand in 1932. She was president of St. Margaret's Residential College for Women in Dunedin, took a prominent part in the social and sporting life of the University, won her blue in hockey, represented the University at lawn tennis, and was one of the best-known and most popular undergraduates of her time. After graduation she held resident posts in New Zealand and England before fulfilling her life-long ambition of working in India, where at first she worked under the Scots Mission at the Women's Hospital, Ajmere, and then went to the Lady Hardinge Medical College for Women at Delhi. On returning to England she held a resident post at the Oxford Eye Hospital, took her Diploma in Ophthalmology, and in more recent months has been working with the Oxford Nutritional Survey. She returned to Oxford a week before Christmas to await the arrival of her baby in February. Dr. Gregory will be much missed by that wide circle of friends in Australasia, India, and Great Britain who had learned to appreciate her great qualities.

By the recent passing of GARDINER WILLIAM TROUTON at the ripe age of 85 Rotherfield has lost an ideal general practitioner, for he possessed a fund of knowledge of humanity and the ailments it is heir to, their prevention and their treatment. Qualifying M.B., B.Ch. of Trinity College, Dublin, in 1888, and holding thereafter appointments, he took his degree of M.D. in 1894. Settling in Sussex, he soon won the respect and the affection of a very wide circle of patients and friends. His courtesy, his infinite care, and his fresh appreciative humour made him indeed a beloved and trusted physician for over thirty years before his retirement. He was chairman and the moving spirit of the Rotherfield Branch of the British Legion, for which post he was admirably fitted on account of his long association with the West Kent Yeomanry. Although over age in the last war, he served throughout the campaign in Egypt, and was present at Gallipoli, thereby securing the coveted Territorial Decoration. A staunch churchman, he was a churchwarden for many years, and gathered round him a following of keen men in the parish of Rotherfield. One of his children has followed her father as a medical practitioner.—W. McA. E.

Dr. JOHN CHRISTOPHER THOMSON, who died at his home in Edinburgh on Dec. 19, aged 80, was born and educated in Lockerbie and later studied arts and medicine at Edinburgh University. He held the following degrees and diplomas: M.A. 1884; M.B., C.M. with honours, 1888; M.D., 1892; D.P.H. Ed. and Glas., 1904; and D.T.M. & H. Camb., 1904. In 1888 Dr. Thomson went to Hong Kong to take charge of the Alice Memorial Hospital, London Missionary Society, when plague was raging in the Colony; he had gained such honour and affection from the leading Chinese that by their special request he was invited to join the Government Medical Service in order to organize measures against plague. From 1897 till his retirement, owing to ill-health, in 1909, he did valuable work in antiplague and antimalaria measures, in connexion with which he was twice mentioned in despatches. He held many public offices, among those of J.P., president of the Hong Kong Branch of the B.M.A., and hon. secretary of, and lecturer in, the Hong Kong College of Medicine. His work in connexion with the last brought him one of the most interesting contacts of a long and varied career, for he had as one of his students for three and a half years the great Chinese reformer, Dr. Sun Yat Sen, and as secretary of the College prepared the medical diploma which was presented to him in the City Hall by Sir William Robinson, the then Governor of the Colony. From his retirement in 1909 until 1923 Dr. Thomson was

engaged in public health work in this country. Among other things he acted as tuberculosis officer for the County of Dumfries and for the Borough of Fulham. Dr. Thomson's outstanding quality was the complete integrity of his mind and character. Inaccuracy of statement and unethical conduct were equally repugnant to him; he was a quiet man, of gentle and courteous manners, and possessed of unflinching tact, but his opinions were definite, and he could be entirely firm when occasion demanded it. His culture and intelligence were high, and it was an education and a pleasure to know him. He had an unusually harmonious family life, marred only by the premature deaths of his two daughters, Dr. Elsie and Dr. Ruby Thomson. He is survived by his son, Dr. Frank Thomson, Dundee, and by his widow, for whom the deepest sympathy is felt by their many friends.

## Medico-Legal

### ASSESSMENT OF BLOOD-GROUP EVIDENCE

Blood-group evidence can show in certain circumstances that a given man is not the father of a given child. An immense amount of work has been done on its scientific foundations, and in the hands of an expert it approximates as nearly to certainty as does any other kind of scientific evidence. On the whole, English courts have been quite ready to accept it when it has been available—in fact, some critics have complained that the experts have had too much of their own way. A case recently heard by Mr. Claud Mullins at the South-West London Police Court indicated the place which such evidence should properly take in our judicial system. The case was not the usual bastardy application, but a summons by a wife against her husband for maintenance. They had been married two or three years, but because each had a war job in different parts of the country they had never made a home together. The husband, however, visited her whenever possible. At the beginning of March, 1943, she bore a child. The husband expressed pleasure on hearing it was coming, and paid all the hospital fees. Two months later, however, he stopped sending her remittances, which had before then been regular, and denied paternity. His solicitors suggested a blood test; the wife, indignantly repudiating the suggestion of adultery, consented. Dr. David Harley, who tested the bloods, found that the husband's group was OM, the wife's AM, and the baby's AMN. Apparently the N factor must have come from another man. Dr. Harley's evidence was the husband's sole reason for opposing the wife's application; he produced no evidence of adultery and did not even name an adulterer, and his reason for disputing paternity never appeared. He was not allowed, under the rule in *Russell v. Russell* (1924) A.C. 687, to deny that he had had access to his wife at the material, or any, time. At first Mr. Mullins was inclined to think that,

albeit very reluctant, he was bound in law to accept the result of the blood test, not because as a man he thought the doctor's right but because as a magistrate he thought that the evidence was legally convincing. Moreover, he recalled that the Select Committee of the House of Lords had published in its report on Lord Merthyr's Bastardy (Blood Tests) Bill, 1939, some very dogmatic statements on the reliability of the test.<sup>1</sup> Later in the case, however, after the wife's sister, with whom she lived, had given evidence that the husband had visited the wife at the time when conception probably took place, and after the husband had been closely cross-examined, Mr. Mullins indicated that he was not prepared to bastardize the child on blood-group evidence alone. He did not, having heard and seen the wife, think she was of a type that commits adultery. The legal presumption that a child born in wedlock is legitimate is very strong, and he was not prepared to upset it solely on scientific evidence. The husband thereupon agreed to make a home for his wife, maintain her and the baby, and accept it as his child. Few who heard the decision doubted its wisdom. It would be an evil day for our courts if they ever felt obliged to elevate scientific evidence into a class by itself, instead of, as at present, keeping it on the same footing as other evidence.

<sup>1</sup> *British Medical Journal*, 1939, 2, 453.

## The Services

Major (temp. Lieut.-Col.) W. L. Brown has been awarded the D.S.O., and Capt. (temp. Major) M. E. M. Herford, M.B.E., M.C., R.A.M.C., a bar to the M.C. in recognition of gallant and distinguished services in Italy.

Major (temp. Lieut.-Col.) I. Fraser, O.B.E., R.A.M.C., has been awarded the D.S.O. in recognition of gallant and distinguished services in Sicily.

Temp. Surg. Lieut. W. B. Wallace, R.C.N.V.R., has been mentioned in dispatches for services in caring for the wounded in H.M.C.S. *Athabaskan* after his ship was attacked by aircraft.

### CASUALTIES IN THE MEDICAL SERVICES

*Missing, presumed to have lost his life.*—Temp. Surg. Lieut. A. D. Bone, D.S.C., R.N.V.R.

*Died from injuries received whilst attempting to reach British lines in Italy.*—Capt. E. T. M. Smith, R.A.M.C.

### DEATHS IN THE SERVICES

By the death on Dec. 24 at Bickington, Devon, of Major-Gen. Sir FOSTER REUSS NEWLAND, K.C.M.G., C.B., C.M.G., A.M.S.(ret.), the dwindling band of officers of the old Army Medical Service has lost a distinguished member a few days before reaching his 82nd birthday. His father was a doctor, and he was educated at Shrewsbury and Trinity College, Dublin, at the latter of which he took the M.B., B.Ch. degrees in 1885. He accepted a commission in the Army Medical Service in the following year, and went on service to India. He served throughout the South African War and won the Queen's medal with five clasps. In the war of 1914-18 he served in France up to 1917, when he went to Italy as D.M.S., and from 1918 to 1922 he held the same administrative rank in Egypt until his retirement in the latter year. He was mentioned in dispatches seven times during the last war, and for his various services he was successively awarded the C.M.G. in 1917, the C.B. in 1918, and the K.G.M.G. in 1919. Other distinctions included the honorary degree of M.D. of Trinity College, Dublin, in 1931; Commander of the Order of St. Maurice and St. Lazarus, Italy; Knight of Grace of the Order of the Hospital of St. John of Jerusalem in 1918; and Silver Medal "Al Milito della Sanita Publica," conferred on him by the King of Italy in 1912. In 1918 he married the daughter of an Italian general, by whom he had one daughter.

Major-Gen. GEORGE SOMERS McLOUGHLIN, C.M.G., D.S.O., R.A.M.C.(ret.), died on Dec. 27, 1943, aged 76. He took the M.B. Durham in 1888 and the B.S. in 1889, and entered the Army Medical Service in the following year. In 1897-98 he served in Uganda and was awarded the D.S.O. and the 3rd class Brilliant Star of Zanzibar, and in 1900-1 won the Queen's medal with four clasps in the South African War. His next active service was with the B.E.F. in France in the 1914-18 war, where he was A.D.M.S. to the Guards Division until 1917, when ill-health necessitated his return to England, and he was mentioned in dispatches and awarded the C.M.G. In 1922 he retired with the rank of major-general.

## Universities and Colleges

### UNIVERSITY OF LONDON

The following candidates have been approved at the examinations indicated:

M.D.—Branch I (Medicine): L. P. R. Fourman, B. F. B. Russell, A. Wardale. Branch II (Pathology): R. M. Haines. Branch V (Hygiene): I. G. Davies.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a quarterly meeting of the Council held on Jan. 13, with Sir Alfred Webb-Johnson, President, in the chair, a resolution of condolence was passed on the death of Dr. G. C. Anderson, Secretary of the British Medical Association. It was reported that Prof. G. Grey Turner had consented to deliver the Hunterian Oration for 1945. The Council agreed that the President should serve as an *ex officio* member of the Committee of Management of the Royal Medical Benevolent Fund. Diplomas of Membership were granted to B. Haigh, A. Taylor, and Margaret R. Todd.

\*Diplomas were granted, jointly with the Royal College of Physicians, as follows:

DIPLOMA IN PUBLIC HEALTH.—J. C. Boyle, Marjorie Swain.  
DIPLOMA IN PSYCHOLOGICAL MEDICINE.—Elizabeth G. W. Barker, H. Coates, Esther A. Davidson, J. E. Glancy, R. Krambach, H. G. Miller, Margaret V. Saul, G. C. Toth.  
DIPLOMA IN LARYNGOLOGY AND OTOTOLOGY.—F. Bauer, G. A. Coggin, K. W. MacKenzie, P. C. Rushton, J. A. B. Thomas.

No. 52

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 1.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases. A blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

\* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

## EPIDEMIOLOGICAL NOTES

## Discussion of Table

In England and Wales the incidence of the common infectious diseases of childhood rose during the week: scarlet fever by 245, whooping-cough by 265, measles by 183, and diphtheria by 80. The notifications of acute pneumonia fell by 82.

In the great towns there were 464 deaths from influenza—that is, 226 fewer than in the preceding week. (For the week ending Jan. 8, influenza deaths numbered 255.) The largest numbers of deaths were recorded in London 56, Liverpool 22, Sheffield 19, Birmingham 16, Manchester 15.

The bigger numbers of cases of the common infections and the recent downward trend. Measles and whooping-cough had fallen in incidence continuously for the past six weeks and scarlet fever for the past four. Scarlet fever rose most steeply in Lancashire by 65 and in London by 61. The rise in whooping-cough occurred mainly in the south. London and the south-eastern counties having 155 cases more than last week. Measles was up in Lancashire by 48, in Hereford by 36, and in London by 31 cases. The increase in Hereford was due to an outbreak in Leominster and Wigmore R.D., with notifications going up from 2 to 35. The only increases of note for diphtheria were in Lancashire, 34 more, and in Warwickshire, 22 more cases.

The notifications of dysentery, 89, which were 7 fewer than in the preceding week, were the lowest for the past eight months. The chief centres of infection were Lancashire 20, and London 18.

In Scotland increases were recorded for diphtheria 37, and scarlet fever 14, while there were 57 fewer notifications of whooping-cough and 35 fewer of measles. There was a steep fall in influenza deaths in the 16 principal towns of Scotland: the totals for the past four weeks were 58, 52, 48, and 23.

In Eire notifications of measles rose from 28 to 58: Dublin C.B. 27, and Laoighis, Thomastown R.D., 20 notifications.

In Northern Ireland the relatively high incidence of diphtheria and scarlet fever was maintained: 46 of 76 cases of scarlet fever were notified in Belfast.

## Vital Statistics

Although the vital statistics of 1943 will not be available for some months, it may be of interest, with the completion of the fourth war year, to compare the trends of infectious diseases as recorded in the weekly returns of the Registrar-General.

## Notifications of Infectious Diseases in England and Wales

Disease	Average 1937-9	1940	1941	1942	1943
Diphtheria .. ..	58,500	46,683	51,091	42,318	35,944
Scarlet fever .. ..	91,158	65,573	69,111	84,932	116,217
Measles .. ..	407,905	495,507	285,803	374,198	371,189
Whooping-cough .. ..	51,403	171,406	65,563	95,859	59,859
Acute pneumonia .. ..	47,736	47,712	50,814	42,487	52,255
Cerebrospinal fever .. ..	1,319	12,791	11,119	6,089	3,380
Dysentery .. ..	3,413	2,643	6,597	7,177	7,772
Paratyphoid and typhoid .. ..	1,676	2,824	4,703	887	707

## Births and Deaths in the Great Towns of England and Wales

	1940	1941	1942	1943
NUMBER OF DEATHS				
All causes .. ..	307,544	267,683	231,579	247,968
Influenza .. ..	5,510	2,993	1,544	6,280
Paratyphoid and typhoid .. ..	56	79	38	26
Scarlet fever .. ..	80	58	55	69
Whooping-cough .. ..	356	1,205	468	605
Diphtheria .. ..	1,409	1,530	937	759
Measles .. ..	458	803	293	397
Diarrhoea and enteritis under 2 .. ..	1,812	1,947	2,283	2,569
DEATHS PER 1,000 CASES				
Paratyphoid and typhoid .. ..	44	31	111	101
Scarlet fever .. ..	2.5	2.1	1.3	1.2
Whooping-cough .. ..	14	16	14	12
Diphtheria .. ..	54	54	39	36
Measles .. ..	2.7	3.4	1.8	2.5
No. of live births .. ..	309,730	262,273	303,114	326,175
Deaths under 1 per 1,000 live births .. ..	62	70	58	58
Stillbirths per 1,000 total births .. ..	39	38	37	33

The declining trend of diphtheria is, perhaps, the most satisfactory feature of the returns, but it is evident that the campaign for immunization must still be vigorously prosecuted.

Cerebrospinal fever is gradually falling to its pre-war level. The small numbers of paratyphoid and typhoid fevers during the past two years are a matter for satisfaction, but the steady rise in the incidence of dysentery during the war is not. The origin of many of the outbreaks of dysentery has been traced to contaminated food. The notifications of scarlet fever during 1943 reached a very high level.

A comparison between years is made difficult by the changing population due to evacuation. The increase in the paratyphoid and typhoid case mortality was due to a relatively greater decrease in paratyphoid than in typhoid—that is, the smaller number of cases of these diseases in 1942 and 1943 contained a much higher proportion of typhoid fever than in 1940 or 1941. There has been a serious rise in childhood mortality from diarrhoea and enteritis. The case mortality of diphtheria shows a substantial improvement.

#### The Week Ending January 8

The returns of infectious diseases in England and Wales during the week included: scarlet fever 1,791, whooping-cough 793, diphtheria 661, measles 515, acute pneumonia 1,608, cerebrospinal fever 92, dysentery 165, paratyphoid 4, typhoid 4, influenza deaths in the great towns numbered 255.

## Medical News

More than two thousand British and Allied doctors and surgeons and members of hospital staffs are being invited to see the British Council film, "Surgery in Chest Diseases," at the Philharmonic Hall, Liverpool, on Thursday, Jan. 27, at 4.30 p.m. Doctors and members of hospital staffs requiring tickets should communicate with the Liverpool Medical Institution or the British Council, 1, Basnett Street, Liverpool, 1.

A meeting of the Council of the Medical Superintendents' Society will be held at the Midland Hotel, Derby, on Saturday, Jan. 29, at 3.30 p.m., and Sunday, Jan. 30, at 10 a.m.

A series of lectures on psychology, suitable for a Diploma in Psychological Medicine, will be held at the Maudsley Hospital, Denmark Hill, S.E.5, on Mondays, Wednesdays, and Fridays, from 2 to 4 p.m., beginning on Jan. 31 and ending on Feb. 21. The fee for the course is £3 3s., payable at the time of enrolment on Jan. 31. All inquiries should be addressed to Dr. W. W. Kay, acting hon. director of the Maudsley Hospital Medical School, Central Pathological Laboratory, West Park Hospital, Epsom. (Tel. Epsom 1408.)

As announced on Jan. 8 (p. 67) the next special film session for doctors and allied personnel will be held at the Odeon Theatre, Broadmead, Bristol, on Sunday, Feb. 6, at 10.45 a.m. An additional film to be shown is the British Council film "Surgery in Chest Diseases."

The Royal Institute of Public Health and Hygiene has arranged a series of lectures on "The Public Health" to be given at 28, Portland Place, W., on Wednesdays, Feb. 9 to March 29, at 3.30 p.m. Admission is free and applications for seats should be made to the secretary.

The Society of Thoracic Surgeons of Great Britain and Ireland will hold a meeting at the Royal Society of Medicine, 1, Wimpole Street, London, W., on Thursday, Feb. 10. At 9.30 a.m. the subject for discussion will be carcinoma of the oesophagus, and at 2 p.m. the subject will be lung abscess. Visitors of the British, Dominions, and Allied medical services, and general surgeons of the E.M.S., will be welcome after obtaining permission from their own higher authorities.

A refresher course in tuberculosis for tuberculosis officers and medical practitioners will be held in Liverpool on Monday, March 27, to Friday, March 31, inclusive. It is being arranged by the committee on education of the Joint Tuberculosis Council and National Association for the Prevention of Tuberculosis, in collaboration with the City Public Health Department and the University of Liverpool. Details of lecturers and subjects will be announced later. The fee for the course is £4 4s., payable in advance. Early application should be made to Dr. Harley Williams, Tavistock House North, Tavistock Square, London, W.C.1, from whom all information may be obtained.

The name of Dr. George Paterson Burr appears in a list of names published by the *London Gazette* as commended for brave conduct when their ships encountered enemy ships, aircraft, submarines, or mines.

There will be found in our advertisement columns this week an advertisement for the post of temporary Assistant Secretary of the British Medical Association.

## Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, *BRITISH MEDICAL JOURNAL*, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1; on receipt of proofs. Authors over-seas should indicate on MSS. If reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Atiology Westcent*, London; SECRETARY, *Medicera Westcent*, London. ADVERTISEMENTS, *Articulate Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh.

### ANY QUESTIONS?

#### Some Unqualified Practitioners

Q.—I should appreciate a short statement as to the differences between, and the beliefs forming the basis of, the following forms of unqualified practice: (a) osteopathy, (b) chiropractic, (c) manipulative surgery, (d) bone-setting.

A.—Osteopathy and chiropractic are both complete systems of "medicine." In osteopathy the theory is that the structural integrity of the mechanism of the body is the most important single factor in maintaining health, and consequently that structural derangement is the predisposing cause of disease. Any tissue may be perverted, but owing to the intimate relationship of the spinal column to the nerves and the vascular system this is the region most often under suspicion. Investigation of what by this "philosophy" are considered to be secondary effects—e.g., chemical, microscopical, bacteriological changes, etc.—follows orthodox lines, but treatment is essentially manipulative to the allegedly perverted or displaced structure. The founder of osteopathy was an orthodox practitioner, Dr. Still of Kansas, and the first school of osteopathy was opened in 1892.

In chiropractic the emphasis falls upon displacements of the vertebrae, which produce pressure effects upon the nerves, and so interfere with the "nerve force" which should flow freely from the brain to the rest of the body if health is to be maintained. Any peripheral effects are thus secondary to the interference with the nervous outflow. The displacements are usually detected by palpation of the spine; the replacement is also manual.

Both osteopathy and chiropractic are much more extensively practised in the U.S.A. than in this country, and in most of the States both are recognized and regulated by law. Their relative numbers and growth are illustrated by the following figures:

Osteopaths (world)	1921: 7,000; 1925: 9,000	} graduates of recognized schools
Chiropractors (U.S.A.)	1921: 10,000; 1926: 25,000	

Manipulative surgery is that form of treatment by manipulation for various local lesions practised by orthodox surgeons—it is indeed doubtful if an unqualified person can legally call himself a manipulative surgeon. No general philosophy of disease as a whole enters into the application of this form of corrective treatment.

Bone-setting is a loose term which defies definition. An orthodox orthopaedic surgeon is obviously often a bone-setter in the truest sense, but the term is usually applied to an unqualified practitioner who claims to cure certain painful and disabling manifestations, usually in joints or muscles, by varying forms of manipulation and adjustment, most of which he regards as secret and peculiar to himself and his fellows. Concisely, a bone-setter is an unqualified manipulator, who may or may not know something of the underlying pathology, physiology, and anatomy of the condition which he treats. The manipulations are usually standardized for each individual joint or region, and, in order to avoid possible legal penalties for damage done, many of the better-known practitioners refuse to treat any case which shows definite physical signs—e.g., x-ray changes, etc.—of organic disease.

#### Control of Tuberculous Patients

Q.—(1) Can any control be exercised over the place of residence of people suffering from tuberculosis of the lung? (2) For example, can such patients live in residential flats? (3) Are they kept under any supervision as to infectivity?

A.—The general powers of local authorities, and the obligations imposed on infectious persons for preventing the spread of infection, contained in the Public Health Act, 1936, apply only in the case of sufferers from the diseases mentioned in that Act and from any diseases to which these powers and obligations are extended by

Orders or Regulations. These powers and obligations are not included in the Regulations under which tuberculosis has to be notified, but which make it the duty of the medical officer of health to "make such inquiries and take such steps as are necessary or desirable for investigating the source of infection, for preventing the spread of infection, and for removing conditions favourable to infection." It will be noted that no obligation is placed on the infectious person himself, and as the M.O.H. is instructed by the Regulations that every notification of tuberculosis and every document relating thereto are to be regarded as confidential, it is obvious that restrictive measures involving exposure of their state are not intended to be applied to patients. Certain sections of the Public Health Act may, however, be applied compulsorily. A local authority may enforce periodical disinfection of houses, rooms, and articles for any infectious disease, including tuberculosis. An L.A. may also apply to a court for an order for the compulsory removal to hospital of an open, demonstrably infectious case of pulmonary tuberculosis if precautions against the spread of infection are not or cannot be taken, if other persons are therefore at risk, and if there is accommodation available for the patient in an institution. This procedure has generally been regarded as unworkable under present conditions, especially with the shortage of beds for even those infectious cases desiring admission, and has never, or practically never, been used.

The answers to the questions are therefore (1) virtually none; (2) yes; (3) they are visited by tuberculosis visitors who advise and assist them in maintaining their own health and preventing the spread of infection to others. If the M.O.H. learns from any source that the habits of an infectious person are specially dangerous to others he will no doubt instruct the visitors to put pressure on the patient to behave more hygienically; perhaps, in cases of gross negligence, reinforcing the admonition by a threat that the above-mentioned power of removal will be used.

#### Vitamin D in Arthritis

Q.—I understand that large doses of vitamin D have been used with alleged success in the treatment of osteo-arthritis. Is there any satisfactory evidence that it is of use in this or in any rheumatic conditions, and, if so, in what doses should it be prescribed?

A.—There is no satisfactory evidence that vitamin D is of any service in osteo-arthritis, and since its action tends to improve calcium assimilation and thus to lead to increased bone density, it would appear to be contraindicated unless senile osteoporosis is the dominant feature rather than the hypertrophic changes and increased bone density of true osteo-arthritis. Reed, Struck, and Steck (*Vitamin D*, Chicago, 1939) treated a mixed group of arthritides with huge doses of vitamin D, 150,000 to 200,000 international units daily, and noted measurable improvement in 74.5%. They do not state in which type of arthritis this occurred, but of the 45 cases only 7 were of the hypertrophic type, and it seems probable that the improvement was in the other types. The use of vitamin D in rheumatoid arthritis in which atrophic changes and osteoporosis are features is a sound therapeutic measure in moderate dosage, 400 to 600 i.u. daily. A popular journal has recently reported remarkable beneficial effects in America from the use of a special form of vitamin D which is prepared by passing a current of electricity through ergosterol instead of irradiation with ultra-violet rays; with this method the toxic effects liable to result from heavy dosage of the vitamin are said not to occur; the benefit was in rheumatoid arthritis and not in osteo-arthritis. I am unaware of any confirmation of these results up to the present.

#### Inheritance of Diabetes

Q.—A youth of 18, in good general condition and free from symptoms, has been put in Grade 4 by a medical board because of diabetes. He has been advised to take a high-carbohydrate diet with zinc-protamine-insulin daily. His sister, aged 12, is a diabetic and has been on insulin for some time past. He hopes to marry, and asks: (a) Would his wife's prospects of happiness in marriage be affected by his having diabetes? (b) Are his chances of begetting children affected? (c) Is he likely to transmit to his children a tendency to the disease?

A.—In *The Diabetic Life* (J. and A. Churchill, 12th edition, 1941, p. 125) R. D. Lawrence writes: "Formerly, in severe diabetes, men were usually impotent and women ceased to menstruate, but insulin usually restores a normal sexual life. Marriage is not dangerous to men, but if a family history is present, full family histories on both sides should be got, the hereditary nature of the case must be considered, and the possibility of the child developing diabetes. . . . When the doctor has pointed out the hereditary possibilities after a full pedigree on both sides has been studied, the parents must take the responsibility of decision, as there are no laws of national eugenics, nor, indeed, any certain laws of diabetic heredity." Some of the factors affecting happiness in marriage would be the reduced expectation of life (intercurrent diseases, such as tuberculosis) and

the trouble of providing suitable diet. The risk of invalidism should not be great. The case would be affected by the economic circumstances and intelligence of the patient. An intelligent man in a good social position might make a success of it, but a dull man in a poor home would be a different matter. As the quotation from *The Diabetic Life* suggests, the chances of begetting children are probably unaffected.

Diabetes, or at least the tendency to develop it, is certainly inherited. As yet, however, there is no general agreement as to the mode of transmission, and in any case it is probable that only some of the bearers of the gene or genes develop the condition—i.e., the co-operation of other factors is necessary if the condition is to become manifest. It would probably be generally agreed that the chance of any particular child being affected is not greater than 1 in 10, and may be considerably less.

#### Hodgkin's Disease and Leukaemia

Q.—Could you inform me of the latest treatment for Hodgkin's disease and leukaemia?

A.—The chief place in the treatment of Hodgkin's disease and of leukaemia is taken by x-ray therapy directed towards the relief of symptoms and the prolongation of life; supporting measures, including iron, arsenic, and ascorbic acid, should not be neglected. Expert pathological diagnosis is essential in Hodgkin's disease, as this term is often used to include not only lymphadenoma verum, but all the lymphadenopathies, from the benign lymphoid follicular reticulosis (which seldom requires x-ray therapy) to the very malignant reticulo-sarcoma (which requires the most intensive x-ray therapy). In an early case of lymphadenopathy, where the involvement is limited to a single group of superficial lymph nodes, excision preceded and followed by a relatively large dose of radiation may result in cure—or at all events disappearance of the disease for a long period. At the other extreme, with generalized disease, the prospect of worth-while palliation need seldom be abandoned.

In splenic irradiation for chronic leukaemia the longest remissions will be obtained if the white cell count is brought down to 6,000 per c.mm.; the practice of stopping x-ray treatment when this comes down to about 20,000 should be condemned. Many cases of chronic lymphatic leukaemia are symptom-free, and do not need irradiation simply because there is an increased lymphocyte count. All cases of chronic myeloid leukaemia require irradiation when the myelocyte count begins to show a progressive increase.

Radio-active phosphorus (by mouth or by injection) gives results in leukaemia similar to those of x-ray therapy, but supplies are not available in this country, as our cyclotrons are engaged on war-work (see *Radiology*, 1942, 39, 573, for American results).

#### Spina Bifida and Incontinence

Q.—A boy aged 8 suffers from permanent incontinence of urine and faeces following nerve damage during an operation for a spina bifida and meningocele of the lumbar region associated with hydrocephalus. Would this boy's condition be improved if the ureters were transplanted into the colon and a permanent colostomy performed?

A.—The effect of transplanting the ureters would be to render the control of the outflow of urine more difficult than ever, and to increase the risk of pyelitis. The permanent colostomy would add a further nursing difficulty without improving the rectal condition, since urine would pass more freely to the anus than to the colostomy opening. Regular wash-outs should control the rectal incontinence by keeping the lower bowel empty. The urinary incontinence can be managed by means of an apparatus to collect the urine, either with or without a suprapubic cystostomy.

#### Anaesthesia for Cystoscopy

Q.—Is pentothal sodium a suitable anaesthetic for use (a) during cystoscopic examination of tuberculous bladders, (b) for over-distension of the bladder, (c) for cystoscopic examination in patients who have a cough from any cause? In the first two types of case I have failed to obtain complete immobility and absolute relaxation; in type (c) cough is liable to occur, and I am under the impression that it cannot be suppressed. I may add that I am using a 2½% solution in out-patients who are unpremedicated.

A.—Pentothal (or the other ultra-short-acting barbiturate, hexobarbitone) if given in sufficient quantity will provide satisfactory anaesthesia for cystoscopy in the medical conditions described. Whether or not it is suitable for out-patients depends on how long the patient is to be kept anaesthetized, and this in turn is associated with the dexterity of the surgeon and his being ready to introduce the cystoscope immediately anaesthesia is induced. These factors decide the amount of pentothal which will be used, and this determines the time taken by the patient before he is ambulatory. Moderately deep anaesthesia is needed to relax the sphincter of the bladder and to prevent the patient reacting to the stimulus of the cystoscope. Deep anaesthesia need be of only extremely short

duration—the actual time for the introduction of the cystoscope into the bladder—and is obtained by the rapid injection of a small quantity of pentothal, say, 0.3 to 0.4 g. The syringe and needle are kept *in situ*, and once the cystoscope is inserted only enough additional pentothal is given to keep the patient quiet. However, if more than half a gramme is used, as is likely if it is given slowly to unpremedicated out-patients with irritable bladders, the recovery time will probably be prolonged enough to put its use for out-patients out of court.

On the whole pentothal should be used for out-patients *only if it is given in a small dose rapidly*. This provides a short period of deep anaesthesia, but, even after this, adequate facilities for recovery must be afforded.

#### Hormones and Cancer

**Q.**—As stilboestrol is apparently used with success for the treatment of prostatic carcinoma, is there any evidence that the prolonged administration of testosterone propionate may be useful in cases of cancer of the breast or of the uterus?

**A.**—I cannot see the analogy between treating carcinoma of the prostate with stilboestrol and treating carcinoma of the breast with testosterone propionate. Unfortunately it is possible to find articles and letters in the literature describing isolated cases treated apparently successfully with every hormone preparation known. There is no incontrovertible evidence that testosterone propionate is of any value in the treatment of carcinoma of the breast.

### INCOME TAX

#### Partnership—Expenses of New Partner

"LAMBDA" joined a partnership on Jan. 1, 1943, in replacement of a partner who left the practice on Sept. 30. "Each partner claims his own expenses." The inspector of taxes has agreed to allow "Lambda" the expenses of the outgoing partner for the previous year, but in fact these expenses cover a period of nine months only.

\* The root difficulty here is that a partnership is assessable to tax for any year in one sum on the amount of the *profits of the firm* for the previous year. In arriving at that amount the expenses deducted can reflect only nine months' expenses of the outgoing partner, though if a locumtenent was employed by the firm in the interval of three months that expense is also deductible. Consequently what is really the only way by which "Lambda" can have the equitable arrangement he desires—i.e., the allowance of a year's expenses from his share of the gross receipts—is by some re-allocation of the gross receipts among the partners themselves.

#### Diploma Expenses

R. H. incurred expenses in taking a special examination. Can they be regarded as deductible in calculating practice profits?

\* No. There are two grounds of objection: (1) that such expenses are personal and not incurred in the carrying on of professional work, and (2) even if that were not the case such expense is of a capital nature, as improving the knowledge of the practitioner.

### LETTERS, NOTES, ETC.

#### Parotitis following Trilene

Dr. F. G. PATRICK writes: Recent correspondence concerning trigeminal paralysis caused by trilene anaesthesia prompts me to inquire whether any anaesthetist has noticed swelling of the parotid glands following its use. Some months ago I gave an anaesthetic consisting of nitrous oxide, oxygen, and trilene to a boy of 9 for the removal of a leg plaster. The anaesthetic lasted about 15 minutes, and the child's recovery was uneventful, but about half an hour afterwards his neck became swollen and painful. When I saw him some 3 hours later he had the typical appearance of a child with mumps. The swelling, which was painful and tender, gradually subsided during the next 24 hours. I have found reference in the literature to bilateral parotitis following anaesthetics, but it has been attributed to the atropine premedication. This patient had no atropine previously, so I can only conclude the anaesthetic itself was responsible for his parotitis.

#### When the Stethoscope should be left in the Bag

Dr. G. H. GRANT DAVIE writes: I have just recovered from acute bronchiolitis. This was accompanied by frequent irritating coughs induced by bronchial and tracheal gurglings, profuse frothy, sticky, mucopurulent spit, with a maximum temperature of 102°, and, what is not so often described, the presence of an uncomfortable dull rending intrapulmonary pain as though the lung was being slowly torn apart. This reached a maximum sharp cutting type of pain when intrapulmonary pressure was raised by coughing or nose-

blowing. Under treatment, in two to three days the acute symptoms lessen, temperature and pulse rate drop, respirations are less hurried and difficult, the pulmonary pain becomes more bearable, or perhaps is only apparent on intrapulmonary effort. These diminishing physical signs and symptoms should amply satisfy the physician in charge. But what is the procedure? Out comes the stethoscope, and the patient is put through a meticulous auscultatory examination involving inspiratory and expiratory effort over an appreciable period, at the end of which he is more or less panting, with increased cardiac rate, and shortly afterwards there is a return of the sickening intrapulmonary pain with increased exudation and cough. Thus physicians ignore the first principle of their teaching that an inflamed part should be kept at rest, and unwittingly cause their patients, who in turn do their best to help, the great disservice of compelling resolving bronchioles to work at pressure. Their clinical sense should tell them that all is well, and that the less disturbance these inflamed surfaces receive the sooner repair will take place, and, what is quite important, the comfort of their patients will be enhanced.

#### Rare Medical Books

There are several rarities to be sold at Messrs. Sotheby's auction room on Jan. 24-6, derived from a number of different collections. Interesting incunabula are the first edition, Bologna, 1487, of Savonarola's *De pulsibus urinis et egestionibus*; and a *Hortus Sanitatis*, Strasburg, 1497. There is a translation by William Ward of Alexis of Piedmont's textbook of diseases, 1595; and two London editions of Th. Barrough's *Method of Physick*, respectively 1590 and 1596. Earlier than these (London, 1552) is a slightly imperfect copy of the textbook of anatomy by Thomas Geminus: more covetable, perhaps, is the Southwark-printed, 1525, *Noble Experience of the Virtuosis Handywarke of Surgery*, whose author was Hieronymus von Braunschweig; and even rarer is a pharmacological treatise by the same author from the same press in 1530. The state of medicine and surgery in England and in France is compared by G. Arnaud in some memoirs, printed 1768, next to which may be mentioned Despierre's monograph on the diseases of sailors, Paris, 1767, and Rostinio's work on venereal disease; Venice, 1556; also from Venice, though not from the same printer, is Susio on fevers and bleeding, 1571. There are two books on preventive medicine by Traffichetti, 1565, and Fonseca, 1602; and in the same category, perhaps, can be placed Philip Moore's *Hope of Health, wherein is contained a goodlie reglemente of life*, London, 1564. This Moore was better known as an almanac producer and prognosticator, though whether he was the original Old Moore is not here affirmed. Among others of lesser interest one may just note two manuscripts. One is interleaved with the seventh edition, 1631, of the *Rieh Storehouse or Treasure for the Diseased*, by G. W. These leaves contain many prescriptions with the names of the seventeenth-century physicians responsible for them. The other is Richard Henshall's *New System of Health*, never published; it was composed in 1728 and dedicated to Drs. Henry Hall, Robert Bostock, and Richard Breech.

#### Resuscitation by Rocking for Heat-stroke

Dr. F. R. W. K. ALLEN writes from Poona: I have been following with interest the various modifications of stretchers for applying Eve's method of resuscitation culminating in the illustration on page 494 of your issue of Oct. 16, 1943. In case of heat hyperpyrexia there is always a danger of failure of respiration. If such cases are treated by Eve's method of resuscitation there will be no need for any interruption in the measures being taken for reduction of the temperature. Both can be carried out simultaneously. It appears that all "heat-stroke stations" should be supplied with a rocking device. I have not met with any support here, and so I should be grateful for your readers' criticism on the subject.

#### Delayed Menarche

Dr. E. FRIEDMANN writes from the Royal Free Hospital: Though it is quite true that the menarche delayed beyond the 16th birthday is not an abnormality in itself, nor does it necessarily cause trouble, there is, however, one important point that needs special emphasis. The girl may be physically well developed and show no signs of endocrine immaturity as the absence of the menstruation might suggest. But from the experience of hundreds of cases of sterility we know that there must be a definite relationship between the onset of the menarche and infertility. Quite a number of patients attending a sterility clinic are those who did not menstruate until the age of 17 or 18, although from then on they had no gross menstrual irregularity. If we consider the katamenia from this important point of view, I should think that a girl who has not started to menstruate by the age of 16 at the latest should be treated with thyroid, oestrogen, and vitamins in an attempt to prevent the development of a hypoplastic uterus. The great urgency of the social problem of infertility should stimulate us to prevent rather than to cure any condition liable to lead to sterility.

# BRITISH MEDICAL JOURNAL

LONDON SATURDAY JANUARY 29 1944

## LOCALIZED SUBCUTANEOUS OEDEMA WITH WEAKNESS OF LIMB MUSCLES A SYNDROME DUE TO POLYARTERITIS NODOSA

BY

RONALD MacKEITH, D.M., M.R.C.P.

*Temporary Surgeon Lieutenant, R.N.V.R.; Medical Specialist, Royal Naval Medical Service*

The three cases of polyarteritis nodosa described here are of interest for several reasons. They all showed as the two salient features a localized soft pitting oedema of the skin of one or more limbs together with asymmetrical muscular weakness—a clinical picture not previously described. Two of these patients recovered from the illness. All three cases were diagnosed in life, the diagnosis being confirmed by biopsy. The three cases were seen in one hospital in a period of 18 months, which suggests that Leishman (1937) was right in suggesting that this disease, though very varied in its forms, should be recognized more frequently. It may be observed that during his period, although polyarteritis was being looked for, in only one other case was it suspected, and this showed a clinical picture very similar to that of the three cases. The biopsies, however, were negative.

### Case I (an Engineer aged 27)

The family history was irrelevant. There was a previous history of a cough for 12 months and of a coryza towards the end of April, 1940. On May 1, 1940, while at work, the patient injured his right calf and had to take to bed. Two days later, while in bed, he found that he had great difficulty in moving the right thigh—attempts causing pain in the groin—and that he was unable to lift his right forearm off the bed or to raise the arm at the shoulder.

On May 6, 1940, he was admitted to St. James Hospital, London. He was of slim build and in fair general condition; his temperature was 99.6° F., the pulse rate 88, and the respiration rate 24. No abnormal signs were found in mouth, lungs, heart, or abdomen; his blood pressure was 135/85 (a week later it was 120/80). A mild degree of clubbing of the finger-nails was present. There was considerable weakness of the right deltoid and biceps muscles, which were tender on palpation. The right upper arm was swollen—the circumference being 9½ in., against 8 in. on the left side—from diffuse soft pitting oedema. The skin was not inflamed. There was no sensory loss or any paraesthesiae at this time or later. The muscles of the right thigh were weak and tender, and pain was felt on externally rotating the flexed thigh. There were two subcutaneous nodules on the outer side of the right calf, but no oedema there. His left arm and leg were normal. The patient was treated by rest in bed and a high vitamin diet (with bexmax, cod-liver oil, ascorbic acid, and iron), and massage at a later stage.

**Investigation on Admission.**—Urine, nothing abnormal. Blood urea, 36 mg. per 100 c.cm. Blood count: R.B.C. 5.5 millions; Hb 92% (Haldane); platelets normal; W.B.C. 12,000—neutrophils 9%, lymphocytes 15%, monocytes 6%. (Nine days later: Hb 97%, W.B.C. 12,000, neutrophils 69%.) Sedimentation rate, normal. Sputum: no tubercle bacilli on 3 examinations; culture pneumococci. Radiograph of chest (May 13, 1940): Increased markings at both bases, and a small amount of fluid or thickened pleura at the left base. (A further chest radiograph two weeks later showed no change.) A radiograph of the right upper arm revealed no abnormality. Cerebrospinal fluid: Clear, colourless, 2 cells per c.mm.;

protein, 40 mg.; globulin nil; chlorides, 740 mg.; W.R. and Lange negative. Blood W.R. and K.R. negative. An electrocardiogram on May 26 showed poor T-waves and slight elevation of ST, with depression of ST<sub>1</sub>. These changes were still present 10 days later.

**Progress in Hospital.**—For 2½ weeks he had a symptomless pyrexia and a rather longer-lasting tachycardia (Fig. 1). The swelling of

FIG. 1.—Temperature and pulse chart of Case I.

the right arm had increased the day after admission to 10½ in. circumference, but in a few days it began to diminish and in two weeks it was gone. The weakness of the right arm and shoulder persisted for 10 days before improving, but had cleared up in 4 weeks. A week after admission there was still tenderness at the insertion of the biceps muscle, and some pain was felt on using the triceps. There was also a tender nodule, about 0.5 cm. in diameter, beside the brachial artery at the level of the biceps tendon. The power of the right thigh improved from the time of admission. A week after admission one small tender subcutaneous nodule was observed on the outer side of the right calf, and also an erythema-nodosum-like lesion of the skin over the shin. On May 11 he complained of pain in the left orbit, but no lesion or oedema was seen. The patient started getting up on June 3, and for a few days after this the dorsum of the right foot showed a little soft oedema. There was no tenderness or weakness of muscles of the legs, and the ankle-jerks were present though not brisk. On June 9, five weeks after admission, he left the hospital quite well.

On May 22 a biopsy specimen was taken of a nodule, 0.3 cm. in diameter, attached to a small subcutaneous vessel in the right arm. The histological report was: "Polyarteritis nodosa in nodule from subcutaneous tissue of arm."

Two and a half years later, in Oct., 1942, he and his private doctor both reported that he had remained perfectly well.

duration—the actual time for the introduction of the cystoscope into the bladder—and is obtained by the rapid injection of a small quantity of pentothal, say, 0.3 to 0.4 g. The syringe and needle are kept *in situ*, and once the cystoscope is inserted only enough additional pentothal is given to keep the patient quiet. However, if more than half a gramme is used, as is likely if it is given slowly to unpremedicated out-patients with irritable bladders, the recovery time will probably be prolonged enough to put its use for out-patients out of court.

On the whole pentothal should be used for out-patients *only if it is given in a small dose rapidly*. This provides a short period of deep anaesthesia, but, even after this, adequate facilities for recovery must be afforded.

#### Hormones and Cancer

**Q.**—As stilboestrol is apparently used with success for the treatment of prostatic carcinoma, is there any evidence that the prolonged administration of testosterone propionate may be useful in cases of cancer of the breast or of the uterus?

**A.**—I cannot see the analogy between treating carcinoma of the prostate with stilboestrol and treating carcinoma of the breast with testosterone propionate. Unfortunately it is possible to find articles and letters in the literature describing isolated cases treated apparently successfully with every hormone preparation known. There is no incontrovertible evidence that testosterone propionate is of any value in the treatment of carcinoma of the breast.

### INCOME TAX

#### Partnership.—Expenses of New Partner

"LAMBDA" joined a partnership on Jan. 1, 1943, in replacement of a partner who left the practice on Sept. 30. "Each partner claims his own expenses." The inspector of taxes has agreed to allow "Lambda" the expenses of the outgoing partner for the previous year, but in fact these expenses cover a period of nine months only.

\* The root difficulty here is that a partnership is assessable to tax for any year in one sum on the amount of the *profits of the firm* for the previous year. In arriving at that amount the expenses deducted can reflect only nine months' expenses of the outgoing partner, though if a locumtenent was employed by the firm in the interval of three months that expense is also deductible. Consequently what is really the only way by which "Lambda" can have the equitable arrangement he desires—i.e., the allowance of a year's expenses from his share of the gross receipts—is by some re-allocation of the gross receipts among the partners themselves.

#### Diploma Expenses

R. H. incurred expenses in taking a special examination. Can they be regarded as deductible in calculating practice profits?

\* No. There are two grounds of objection: (1) that such expenses are personal and not incurred in the carrying on of professional work, and (2) even if that were not the case such expense is of a capital nature, as improving the knowledge of the practitioner.

### LETTERS, NOTES, ETC.

#### Parotitis following Trilene

Dr F. G. PATTRICK writes: Recent correspondence concerning trigeminal paralysis caused by trilene anaesthesia prompts me to inquire whether any anaesthetist has noticed swelling of the parotid glands following its use. Some months ago I gave an anaesthetic consisting of nitrous oxide, oxygen, and trilene to a boy of 9 for the removal of a leg plaster. The anaesthetic lasted about 15 minutes, and the child's recovery was uneventful, but about half an hour afterwards his neck became swollen and painful. When I saw him some 3 hours later he had the typical appearance of a child with mumps. The swelling, which was painful and tender, gradually subsided during the next 24 hours. I have found reference in the literature to bilateral parotitis following anaesthetics, but it has been attributed to the atropine premedication. This patient had no atropine previously, so I can only conclude the anaesthetic itself was responsible for his parotitis.

#### When the Stethoscope should be left in the Bag

Dr. G. H. GRANT DAVIE writes: I have just recovered from acute bronchiolitis. This was accompanied by frequent irritating coughs induced by bronchial and tracheal gurglings, profuse frothy, sticky, mucopurulent spit, with a maximum temperature of 102°, and, what is not so often described, the presence of an uncomfortable dull rendering intrapulmonary pain as though the lung was being slowly torn apart. This reached a maximum sharp cutting type of pain when intrapulmonary pressure was raised by coughing or nose-

blowing. Under treatment, in two to three days the acute symptoms lessen, temperature and pulse rate drop, respirations are less hurried and difficult, the pulmonary pain becomes more bearable, or perhaps is only apparent on intrapulmonary effort. These diminishing physical signs and symptoms should amply satisfy the physician in charge. But what is the procedure? Out comes the stethoscope, and the patient is put through a meticulous auscultatory examination involving inspiratory and expiratory effort over an appreciable period, at the end of which he is more or less panting, with increased cardiac rate, and shortly afterwards there is a return of the sickening intrapulmonary pain with increased exudation and cough. Thus physicians ignore the first principle of their teaching that an inflamed part should be kept at rest, and unwittingly cause their patients, who in turn do their best to help, the great disservice of compelling resolving bronchioles to work at pressure. Their clinical sense should tell them that all is well, and that the less disturbance these inflamed surfaces receive the sooner repair will take place, and, what is quite important, the comfort of their patients will be enhanced.

#### Rare Medical Books

There are several rarities to be sold at Messrs. Sotheby's auction room on Jan. 24-6, derived from a number of different collections. Interesting incunabula are the first edition, Bologna, 1487, of Savonarola's *De pulsibus viriis et egestionibus*; and a *Hortus Sanitatis*, Strasburg, 1497. There is a translation by William Ward of Alexis of Piedmont's textbook of diseases, 1595; and two London editions of Th. Barrough's *Method of Physick*, respectively 1590 and 1596. Earlier than these (London, 1552) is a slightly imperfect copy of the textbook of anatomy by Thomas Geminus: more covetable, perhaps, is the Southwark-printed, 1525, *Noble Experience of the Vertuous Handywarke of Surgerv*, whose author was Hieronymus von Braunschweig; and even rarer is a pharmacological treatise by the same author from the same press in 1530. The state of medicine and surgery in England and in France is compared by G. Arnaud in some memoirs, printed 1768, next to which may be mentioned Despierre's monograph on the diseases of sailors, Paris, 1767, and Rostinio's work on venereal disease, Venice, 1556; also from Venice, though not from the same printer, is Susio on fevers and bleeding, 1571. There are two books on preventive medicine by Trafichetti, 1565, and Fonseca, 1602; and in the same category, perhaps, can be placed Philip Moore's *Hope of Health*, wherein is contained a goodlie regimene of life, London, 1564. This Moore was better known as an almanac producer and prognosticator, though whether he was the original Old Moore is not here affirmed. Among others of lesser interest one may just note two manuscripts. One is interleaved with the seventh edition, 1631, of the *Rich Storehouse or Treasure for the Diseased*, by G. W. These leaves contain many prescriptions with the names of the seventeenth-century physicians responsible for them. The other is Richard Henshall's *New System of Health*, never published; it was composed in 1728 and dedicated to Drs. Henry Hall, Robert Bostock, and Richard Brecch.

#### Resuscitation by Rocking for Heat-stroke

Dr. F. R. W. K. ALLEN writes from Poona: I have been following with interest the various modifications of stretchers for applying Eve's method of resuscitation culminating in the illustration on page 494 of your issue of Oct. 16, 1943. In case of heat hyperpyrexia there is always a danger of failure of respiration. If such cases are treated by Eve's method of resuscitation there will be no need for any interruption in the measures being taken for reduction of the temperature. Both can be carried out simultaneously. It appears that all "heat-stroke stations" should be supplied with a rocking device. I have not met with any support here, and so I should be grateful for your readers' criticism on the subject.

#### Delayed Menarche

Dr. E. FRIEDMANN writes from the Royal Free Hospital: Though it is quite true that the menarche delayed beyond the 16th birthday is not an abnormality in itself, nor does it necessarily cause trouble, there is, however, one important point that needs special emphasis. The girl may be physically well developed and show no signs of endocrine immaturity as the absence of the menstruation might suggest. But from the experience of hundreds of cases of sterility we know that there must be a definite relationship between the onset of the menarche and infertility. Quite a number of patients attending a sterility clinic are those who did not menstruate until the age of 17 or 18, although from then on they had no gross menstrual irregularity. If we consider the katamenia from this important point of view, I should think that a girl who has not started to menstruate by the age of 16 at the latest should be treated with thyroid, oestrone, and vitamins in an attempt to prevent the development of a hypoplastic uterus. The great urgency of the social problem of infertility should stimulate us to prevent rather than to cure any condition liable to lead to sterility.

## LOCALIZED SUBCUTANEOUS OEDEMA WITH WEAKNESS OF LIMB MUSCLES A SYNDROME DUE TO POLYARTERITIS NODOSA

BY

RONALD MacKEITH, D.M., M.R.C.P.

*Temporary Surgeon Lieutenant, R.N.V.R.; Medical Specialist, Royal Naval Medical Service*

The three cases of polyarteritis nodosa described here are of interest for several reasons. They all showed as the two salient features a localized soft pitting oedema of the skin of one or more limbs together with asymmetrical muscular weakness—a clinical picture not previously described. Two of these patients recovered from the illness. All three cases were diagnosed in life, the diagnosis being confirmed by biopsy. The three cases were seen in one hospital in a period of 18 months, which suggests that Leishman (1937) was right in suggesting that this disease, though very varied in its forms, should be recognized more frequently. It may be observed that during this period, although polyarteritis was being looked for, in only one other case was it suspected, and this showed a clinical picture very similar to that of the three cases. The biopsies, however, were negative.

### Case I (an Engineer aged 27)

The family history was irrelevant. There was a previous history of a cough for 12 months and of a coryza towards the end of April, 1940. On May 1, 1940, while at work, the patient injured his right calf and had to take to bed. Two days later, while in bed, he found that he had great difficulty in moving the right thigh— attempts causing pain in the groin—and that he was unable to lift his right forearm off the bed or to raise the arm at the shoulder.

On May 6, 1940, he was admitted to St. James Hospital, London. He was of slim build and in fair general condition; his temperature was 99.6° F., the pulse rate 88, and the respiration rate 24. No abnormal signs were found in mouth, lungs, heart, or abdomen; his blood pressure was 135/85 (a week later it was 120/80). A mild degree of clubbing of the finger-nails was present. There was considerable weakness of the right deltoid and biceps muscles, which were tender on palpation. The right upper arm was swollen—the circumference being 9½ in., against 8 in. on the left side—from diffuse soft pitting oedema. The skin was not inflamed. There was no sensory loss or any paraesthesiae at this time or later. The muscles of the right thigh were weak and tender, and pain was felt on externally rotating the flexed thigh. There were two subcutaneous nodules on the outer side of the right calf, but no oedema there. The left arm and leg were normal. The patient was treated by rest in bed and a high vitamin diet (with bexax, cod-liver oil, ascorbic acid, and iron), and massage at a later stage.

**Investigation on Admission.**—Urine, nothing abnormal. Blood urea, 36 mg. per 100 c.cm. Blood count: R.B.C. 5.5 millions; Hb 92% (Haldane); platelets normal; W.B.C. 12,000—neutrophils 79%, lymphocytes 15%, monocytes 6%. (Nine days later: Hb 97%, W.B.C. 12,000, neutrophils 69%.) Sedimentation rate, normal. Sputum: no tubercle bacilli on 3 examinations; culture pneumococci. Radiograph of chest (May 13, 1940): Increased markings at both hila, and a small amount of fluid or thickened pleura at the left base. (A further chest radiograph two weeks later showed no change.) A radiograph of the right upper arm revealed no abnormality. Cerebrospinal fluid: Clear, colourless, 2 cells per c.mm.;

protein, 40 mg.; globulin nil; chlorides, 740 mg.; W.R. and Lange negative. Blood W.R. and K.R. negative. An electrocardiogram on May 26 showed poor T-waves and slight elevation of ST, with depression of ST. These changes were still present 10 days later.

**Progress in Hospital.**—For 2½ weeks he had a symptomless pyrexia and a rather longer-lasting tachycardia (Fig. 1). The swelling of

FIG. 1.—Temperature and pulse chart of Case I.

the right arm had increased the day after admission to 10½ in. circumference, but in a few days it began to diminish and in two weeks it was gone. The weakness of the right arm and shoulder persisted for 10 days before improving, but had cleared up in 4 weeks. A week after admission there was still tenderness at the insertion of the biceps muscle, and some pain was felt on using the triceps. There was also a tender nodule, about 0.5 cm. in diameter, beside the brachial artery at the level of the biceps tendon. The power of the right thigh improved from the time of admission. A week after admission one small tender subcutaneous nodule was observed on the outer side of the right calf, and also an erythema-nodosum-like lesion of the skin over the shin. On May 11 he complained of pain in the left orbit, but no lesion or oedema was seen. The patient started getting up on June 3, and for a few days after this the dorsum of the right foot showed a little soft oedema. There was no tenderness or weakness of muscles of the legs, and the ankle-jerks were present though not brisk. On June 9, five weeks after admission, he left the hospital quite well.

On May 22 a biopsy specimen was taken of a nodule, 0.3 cm. in diameter, attached to a small subcutaneous vessel in the right arm. The histological report was: "Polyarteritis nodosa in nodule from subcutaneous tissue of arm."

Two and a half years later, in Oct., 1942, he and his private doctor both reported that he had remained perfectly well.

**Case II (a House-painter aged 63)**

This man had had a chronic cough for many years. He took alcoholic drinks in moderation only. On Nov. 5, 1940, he developed "numbing pain" in the lumbar region and shoulders radiating down the arms. There was no weakness of the limbs. Two days later his ankles began to swell and he became short of breath. On Nov. 11 he was admitted to St. James Hospital.

On admission his general condition was fair. His temperature was 97.6° F., pulse 84 regular, and respirations 20. The heart was normal in size and sounds; the brachial arteries were thickened. There was soft pitting oedema ++ of the ankles, but nothing else to suggest congestive heart failure. He was not orthopnoeic. The lungs showed signs of diffuse bronchitis, but there was little sputum and no haemoptysis.

**Investigations on Admission.**—The urine was normal. There were moderate anaemia and a leucocytosis (R.B.C. 3.5 millions, Hb 77%; W.B.C. 15,200—neutrophils 85%, eosinophils 1%, lymphocytes 11%, monocytes 3%). The blood W.R., K.R., and gonococcal complement-fixation test were negative. The blood sedimentation rate was very rapid—53 mm. on 100 mm. column at 1 hour. The sputum showed no tubercle bacilli; one culture yielded a fair growth of *Friedländer's bacillus*. An x-ray film of the chest showed only the increase in vascular markings common in chronic bronchitis. Radiographs of the limbs revealed no abnormality in bones or joints. The blood urea six weeks after admission was 60 mg. per 100 c.cm., and

left wrist and hand. On the right side there was now no weakness or pain.

On Dec. 6 and 7 he complained of a "different sort of pain" in the abdomen. There was tenderness at the renal angles, and the urine, previously normal, contained albumin, with many red cells and a few leucocytes in the deposit. Some albumin and blood were present in the urine every day from this time till his death five weeks later; and in the last three weeks of his life there were increasing numbers of granular casts. On Dec. 6 it was observed that a mild clubbing of the finger-nails had developed since his admission.

On Dec. 9 he had a severe pain in the left leg and tenderness in the lateral part of the left popliteal fossa, but no fresh oedema. A week later he was becoming drowsy and losing ground. There was now oedema of the ankles, the back of the left thigh, and the left upper arm. The blood count on Dec. 17 showed Hb 72%, W.B.C. 15,600 (neutrophils 80%, eosinophils 5%). He was given a transfusion of a pint of citrated blood, and two days later the blood count was Hb 80%, W.B.C. 15,600 (neutrophils 84%, eosinophils 4%).

He was now (Dec. 19) complaining of severe pain, and the oedema was present in the right thigh as well as the left, and there was a manifest left wrist-drop. He was started on injections of vitamin B<sub>1</sub>,

Fig. 2.—Case II. Photomicrograph showing necrosis of arterial wall. Stained haematoxylin-eosin. ( $\times 95$ .)

Fig. 3.—Case II. Photomicrograph showing polymorph infiltration in vessel wall. Stained haematoxylin-eosin. ( $\times 140$ .)

the plasma protein at this time showed a great rise in albumin. Total protein, 9.9% (normal 5.6 to 7.8%); albumin 7.55% (normal 3.4 to 4.9%); globulin 2.35% (normal 1.2 to 2.9%).

The patient was treated by rest in bed, with bexam, iron, and theophylline by mouth and simple analgesics for the pains.

**Progress in Hospital.**—Four days after admission he developed pain in the legs. The calf muscles were tender and movements of the ankle-joints were painful and weak. The ankle-jerks were absent, the knee-jerks faint, the plantar responses flexor, and the abdominal reflexes present. There was no pain or oedema in the upper limbs at this stage, but the triceps-jerks were absent. No inflammation of the skin or any nodules were present at this or any later stage.

Though the oedema of the feet persisted, the pain in the legs cleared up in a week; but before it had gone pain developed at both elbows. On Nov. 17 neither elbow could be fully extended; the right ulnar nerve was tender but not the left. In contrast there was pitting oedema of the dependent skin at the left elbow, but none on the right. There was also tenderness deep in the right antecubital fossa. A blood count at this time showed no leucocytosis (W.B.C. 6,200), though the B.S.R. was still very rapid—48 mm. at 1 hour. On Nov. 23 pain and soft pitting oedema had appeared at the back of the left thigh, and the pain at the left elbow was worse.

On Nov. 27 the patient complained of paraesthesiae in the right hand; but the legs and arms were much more comfortable, and the swelling at the left elbow began to diminish. A week later, however, he had a severe pain in the left forearm, with tinglings in the left hand, diffuse swelling of the left forearm, and weakness of the

2 mg. on alternate days. On Dec. 24 he was definitely better, with less pain and oedema but some mild paraesthesiae of the hands and feet. The knee, ankle, triceps, and supinator jerks were absent, and the responses from the biceps were faint. The blood pressure was 150/110; there were no signs of congestive heart failure.

The anaemia and leucocytosis were both increasing (Hb 66%; W.B.C. 22,000, neutrophils 97%, on Jan. 3, 1941). He became steadily weaker, his face getting thinner, with an earthy pallor. Oedema now appeared in the right as well as the left arm and increased, and in the legs it became generalized. A course of sulphapyridine was without any good effect. He died on Jan. 12, 1941.

The biopsy report on material taken on Dec. 9, 1940, from subcutaneous tissues and flexor muscles of the left arm was: "Polyarteritis nodosa. Hyaline necrosis of wall of small artery with surrounding acute purulent inflammatory reaction." (Figs. 2 and 3.)

**Necropsy.**—A necropsy was made the day after death. The bronchi contained much mucus and were somewhat dilated at their terminations. Both lower lobes showed diffuse bronchopneumonia. The heart muscle appeared quite normal. There were lines of redness along the descending branches of the right coronary artery, but no nodules or aneurysms. Atheromatous patches were present in both coronary arteries and in the aorta. No nodules were seen on the mesenteric vessels. The liver showed only slight venous congestion. Both kidneys had a smooth surface mottled from many

cortical infarcts. On section the cortex was of normal width; there were two small circular areas suggestive of aneurysm.

**Histological Report.**—The kidneys showed diffuse chronic nephritis and focal ischaemic nephritis, and also severe chronic purulent inflammation and necrosis of arcuate arteries, some with canalized organized thrombosis. Aneurysmal dilatation of an artery and a purulent infarct of the cortex were also seen. There was chronic purulent inflammation and necrosis of coronary arteries of the heart and of arteries in the mesentery. Tissue from the axilla showed chronic purulent inflammation of the axillary artery and of its branches in adherent nerve and muscle. Changes in other organs were bronchopneumonia, chronic septic spleen, congestion of the liver, and fibrosis of the myocardium.

### Case III (an Escalator Engineer aged 58)

This patient had a history of recurrent coughs. He took no alcoholic drinks. About August 10, 1941, he developed aches and pains all over and a dull pain at the navel. There were night sweats, and he noticed that he was passing less urine. He had an occipital headache, poor vision and weeping eyes, and some attacks of faintness. His appetite remained good. A week after the onset of these symptoms he began suddenly to have numbness and tinglings and weakness of the hands, progressing to uselessness, and similar paraesthesiae and a slighter degree of weakness of the legs and feet. Two weeks after the illness began the left side of his face became puffy and the ankles swelled. He was admitted to St. James' Hospital on Sept. 1, 1941.

He was in fair general condition, of sallow complexion; temperature 98°, pulse regular 76, vessel not thickened; respirations rapid (44) but not distressed. The heart size and sounds were normal. There was no orthopnoea; the lungs were clear. There was no venous engorgement or hepatic enlargement; his blood pressure was

peripheral neuritis. The patient was treated by rest in bed with a high vitamin diet. He was given aneurin 10 mg. by intramuscular injection daily for four days, and splints and physiotherapy for the limbs.

**Investigations.**—Circulation times (Sept. 12) normal (ether 8 and 10 seconds; cyanide 15 and 15 seconds). An x-ray film of the chest showed no evidence of disease of the lungs, heart, or mediastinum. Blood W.R. and K.R., negative. Blood urea variable—70 mg. per 100 c.cm. (Sept. 4), 36 mg. (Sept. 16), 70 mg. (Sept. 23). Plasma proteins (Sept. 16) were very high from excessive amount of albumin (total 8.45%—albumin 5.9, globulin 2.55; albumin/globulin ratio 2.3 : 1 (normal values: total 5.6–7.8%; albumin 3.4–4.9, globulin 1.2–2.9; albumin/globulin ratio 2–3 : 1). A blood count on admission (Sept. 2) showed anaemia and a neutrophil leucocytosis. (R.B.C. 4.3 millions, Hb 68%, C.I. 0.8; group O; W.B.C. 9,800—neutrophils 84%, eosinophils 4%, lymphocytes 10%, monocytes 2%.) Serum salts (Sept. 23): chloride 580 mg., potassium 14.5 mg., sodium 324 mg. (normal values: 560–620, 16–20, 325–350).

**Progress in Hospital.**—During his 3½ months in hospital the patient's temperature was often raised (Fig. 4). A course of sulphathiazole started on Sept. 13 had no effect. The blood pressure—200/110 on admission and 225/135 two days later—gradually fell to 160/90 (Oct. 23). The abnormal urinary constituents gradually diminished to a little albumin with a few red cells in the deposits. The oedema varied but never disappeared. There were never any signs of heart failure, right- or left-sided. The pain in the limbs varied; at one time he complained of shooting pains, but chiefly of the numbness and progressive weakness of the hands. The anaemia increased; three weeks after admission the Hb was 48%, with W.B.C. 7,200 (neutrophils 79%, eosinophils 7%).

On Oct. 1, a month after admission, he developed diarrhoea. The stools contained no mucus, blood, parasites, or pathogenic organisms.

FIG. 4.—Temperature chart of Case III.

200/110. Slight tenderness was felt in the loins. The urine contained much albumin, the deposit showing many red cells, a few leucocytes, and some hyaline casts; no organisms were seen or grown on culture. There was much soft pitting oedema of the upper limbs, especially in the dependent part of the forearms and near the elbows; this was more extensive on the right side. There was also soft oedema behind the ankles, especially on the left. The face was free of oedema.

Examination of the nervous system revealed no defect of the cranial nerves. Both deltoids showed some weakness. On the right side there was slight power of flexion of the fingers but complete wrist- and finger-drop, and flexion and extension of the elbow were weak. On the left side he could not oppose the thumb and fourth finger, but flexion and extension of fingers and of wrist were good; there was fair power of flexion of the elbow but considerable weakness of extension. The lower limbs showed slight general weakness. The right triceps, biceps, and supinator jerks were absent, while on the left they were respectively sluggish, normal, and sluggish. The left knee-jerk was brisker than the right; the ankle-jerks were both sluggish. The plantar responses were flexor, the lower abdominal reflexes absent, and the upper normal.

The electrical reactions of the muscles were tested. In the left upper limb these were normal. On the right all muscles reacted to galvanism; to faradism the triceps and extensor muscles of wrist and fingers did not react; the deltoid and biceps reacted weakly; and the muscles of the flexor aspect of the forearm and the intrinsic muscles of the hand reacted normally.

There was on the right a gross loss of sensation of the hand and lower part of the forearm; and on the left, of the hand only. The legs showed diminished sensibility to light touch, of stocking distribution. Position and vibration sense were good. There was no tenderness of the muscles of the upper or lower limbs.

The combination of an asymmetrical polyneuritis with oedema suggested the probability of polyarteritis nodosa. Dr. E. A. Blake Pritchard saw the case; he thought it was not a syndrome due to

Per rectum several small submucous nodules could be felt. Sigmoidoscopy showed a normal mucosa. By the middle of October there was much soft oedema in the lumbar region as well as in the elbow regions and at the ankles. The muscular weakness had increased in the left wrist, in both arms, and in the dorsiflexors of the ankles. There was marked wasting of the intrinsic muscles of the hands and of all the limbs. The loss of pinprick perception in the hands was more extensive. In the feet there was analgesia on the right to the midfoot and on the left to the ankle.

On Oct. 23 the pyrexia became more severe without evident cause. On Oct. 27, as the anaemia and leucocytosis persisted (Hb 56%, W.B.C. 10,200—neutrophils 81%, eosinophils 2%), he was given a blood transfusion. During the following week he developed a cough and fever, with diarrhoea and signs of consolidation of the right lower lobe (Nov. 5). He was given a course of sulphapyridine, and the fever and diarrhoea cleared up. For a time he seemed to be losing ground, but at the end of November he was feeling better, the oedema was lessening, and no eosinophils were seen in a blood count (Hb 58%, W.B.C. 8,600—neutrophils 74%). The chest still gave many moist sounds. He continued to improve, though the hands and fingers were becoming contracted despite splinting and so on. At his own request he went home on Dec. 23, 1941, though he was still too weak to sit up in bed by himself.

**Further Progress.**—At home he remained in bed for three months, improving steadily. Six months after leaving the hospital he came to the out-patient department. His face was fat and ruddy; there was no oedema anywhere. Both hands were wasted and contracted—on the left a claw-hand, but on the right flexion at the metacarpophalangeal joints. The power in the upper arms and elbows was fair. The blood pressure was 245/150, and he had some morning headaches and giddiness. In Oct., 1942, he wrote to say that he was feeling fine; the left hand was still weak and contracted; but the right, which had been the worse, he was able to use for shaving and writing. The legs were still improving, and he could walk a mile or so.

**Biopsy Reports.**—A week after admission a biopsy specimen was taken of skin, subcutaneous tissue, and muscle from the back of the right forearm. The report on this was: "Slight chronic inflammation of fragment of skin, and fibrosis and degeneration of fragments of voluntary muscle. No evidence of polyarteritis nodosa." A second biopsy was made a month later (Oct. 9, 1941). The report on this was: "Degeneration and slight fibrosis of voluntary muscle. Changes consistent with polyarteritis nodosa in one small artery." (Fig. 5.)

FIG. 5.—Case III. Photomicrograph showing inflammatory reaction in vessel wall. Stained haematoxylin-eosin. ( $\times 190$ .)

### Discussion

Three cases of polyarteritis nodosa, in which the diagnosis was confirmed by biopsy, were seen in 18 months. In a further case, clinically similar, the biopsies were negative. (This was a woman, aged 66, who had had diabetes mellitus and probably hypertension for years. She developed stiffness, pain, and weakness in both forearms, with paraesthesiae in the fingers. Much soft pitting oedema of the forearms occurred, with some contracture of the fingers. There was cardiac hypertrophy, but no evidence of congestive heart failure. She had high plasma proteins; total 7.6% (normal 5.6 to 7.8%)—albumin 5.35% (normal 3.4 to 4.9%), globulin 2.25% (normal 1.2 to 2.9%). After two months the right arm and hand improved; the left remained contracted. Though the clinical picture and the high plasma proteins closely resembled the three cases described below, two biopsies showed no evidence of polyarteritis nodosa; this case therefore cannot be considered as proved to be polyarteritis nodosa.)

The chief features of the three proved cases are summarized in the Table. They showed, as the salient features, localized soft oedema of the subcutaneous tissues of one or more limbs, with asymmetrical muscular weakness. The aetiology of polyarteritis nodosa is still without any definite conclusion, but it is interesting that two of the cases started with aches all over and the other shortly after a coryza. All three showed a leucocytosis, but eosinophilia was not a feature. Skin nodules were present in one case only. (Harris *et al.* (1939) pointed out that eosinophilia and nodules are too rare to be of practical value in diagnosis.) In the two cases in which the estimation was made, the total plasma proteins were very high owing to increase of plasma albumin. This finding may be of diagnostic value. The treatments employed were simple: rest in bed, a high vitamin diet supplemented by injections of vitamin B<sub>1</sub>, and splinting and massage for the limbs. The progress of Case I suggests that it is possible to recover completely, while

in Case III there was apparently complete recovery from the acute attack, though certain sequelae remained.

### Summary of Cases

	Case I	Case II	Case III
Sex and age .. ..	M. 27	M. 63	M. 58
Previous history .. ..	12 months' cough; recent coryza	Chronic bronchitis	2 years' recurrent bronchitis
Onset .. ..	Sudden weakness right arm and thigh	Pains in back and dyspnoea	Aches all over
Oedema .. ..	Right upper arm	Successively in ankles, left elbow, left thigh, right elbow, and both legs	Elbows, forearms, ankles, and lumbar region
Nodules .. ..	2 in skin of leg	None	In rectal mucosa
Muscular weakness .. ..	Right arm and thigh	Left wrist-drop, etc.	Right wrist-drop, etc.
Muscle tenderness .. ..	Yes	Yes	No
Contractures of hands .. ..	No	No	Yes (late)
Reflexes .. ..	—	Impaired or absent in affected limbs	Asymmetrically impaired
Sensory disturbance .. ..	None	Paraesthesiae	Paraesthesiae; anaesthesiae
B.P. on admission .. ..	135/85	150/110 (five weeks after admission)	200/110
Urinary abnormalities .. ..	None	None at first; then albumin, blood, and casts	Albumin ++
Lungs .. ..	Thickened pleura (x-ray)	Increasing bronchitis	Intercurrent pneumonia
Clubbing of nails .. ..	Mild	Mild	None
Anaemia (Hb %) .. ..	92%	77%, falling to 57%	68%, falling to 56%; normal six months later
Leucocytosis .. ..	12,000 and 12,000	6,200 to 22,000	10,200 to 7,200
Eosinophils % .. ..	0.0	1.0, 0.5, 4.0, 0.0	4.7, 2.2, 0
Plasma proteins (%) .. ..	—	—	—
Total (normal 5.6-7.8) .. ..	—	9.9	8.45
Albumin ( " 3.4-4.9) .. ..	—	7.55	5.9
Globulin ( " 1.2-2.9) .. ..	—	2.35	2.55
Biopsy .. ..	Positive	Positive	Neg. Pos.
Course of disease .. ..	Recovered in one month. Remains well 2½ years later	Died after two months' illness	Recovered after six months; with residual contractures of hands and weakness of legs

### Summary

Three cases showing localized soft oedema of the subcutaneous tissues of the limbs with asymmetrical muscular weakness are described. The diagnosis of polyarteritis nodosa was confirmed by biopsy. A large increase in plasma albumin was found in the two cases in which this estimation was done. One patient recovered completely, one recovered from the acute illness with muscular contractures and hypertension, and one died.

I thank Dr. W. Allen Daley, Medical Officer of Health to the London County Council, and Dr. N. S. Craig, Medical Superintendent of St. James Hospital, for permission to publish these cases. I wish also to thank Miss E. Edwards, S.R.N., Miss Westlake, S.R.N., Dr. M. L. Playfair, and Dr. A. B. Britton for their help.

The University Extension and Tutorial Classes Council, in co-operation with the Provisional National Council for Mental Health, will hold this year, provided enough applications are received, the usual course for medical practitioners on mental deficiency and allied conditions. The lectures will be given at the London School of Hygiene and Tropical Medicine, Keppel Street, Bloomsbury, and the date fixed for the course is April 24 to May 5. The University of London will grant certificates of attendance to those who attend regularly, taking both theoretical and practical work. The registration fee, to be paid at the time of application, is 10s. 6d., and the fee for the course is £5 15s. 6d. Cheques should be made payable to the Provisional National Council for Mental Health, and crossed Barclays Bank Ltd. All communications with reference to the course should be addressed to Miss Evelyn Fox, C.B.E., c/o University Extension Department, University of London, 39, Queen Anne Street, W.1. Intending candidates are asked to apply at the earliest possible date, but in any case by March 18. Detailed time-tables and other information will be sent out a week before the course opens to each person proposing to attend. Should the course have to be cancelled all fees will be returned.

## EMPHYSEMA OF THE LUNGS\*

BY

RONALD V. CHRISTIE, M.D., D.Sc., F.R.C.P.

*Professor of Medicine in the University of London, Physician to St. Bartholomew's Hospital*

## PART II

## Physical Signs

The mechanism by which loss of pulmonary elasticity may lead to enlargement of the thoracic cage has already been discussed. The diaphragm because it is no longer pulled upwards by the lungs, descends and becomes less convex, and its movement on inspiration is greatly diminished. Because of its loss of tone the diaphragm may also present an irregular outline in the radiograph. The intercostal muscles will also be unable to perform their proper function, as they are concerned with moderate inspiration and the chest is already expanded when inspiration begins, to expand the chest further the accessory muscles will have to be used, particularly the pectorals, and these raise the front of the chest as a whole in a "heaving" manner, such as occurs in a normal individual towards the end of a forced inspiration. Thus inspiration has to be performed by means of an unnatural inspiratory effort, and the patient with emphysema will encounter even greater difficulty in deflating his lung. Normally, expiration is largely, if not wholly, a passive act: the thoracic cage is pulled inwards by the elastic recoil of the lung. With loss of elasticity there must be loss of elastic recoil, so that if the lung is to be deflated it has to be squeezed. The respiratory musculature was not built for this task, and the intercostals have to be assisted by the accessory muscles of expiration: the muscles of the abdominal wall can often be felt to contract on expiration, which is prolonged as it is in other conditions, such as asthma and tracheal obstruction, in which the lungs have to be compressed by an active muscular effort. With so extensive an impairment of both inspiration and expiration it is not surprising that the vital capacity and chest expansion are reduced.

Many of the physical signs which can be elicited from the lung itself can be explained on the basis of loss of elasticity. I have already emphasized that, in the inelastic lung, distribution of expansion might be expected to be far from equal and should be greatest where the force is applied, which is on the peripheral parts under the visceral pleura. It would be reasonable to expect that, as the application of this force is repeated many thousands of times daily, the superficial air sacs next the pleura would in time become over-distended. With over-distension their supporting framework would be lost and further stretching would become easier, so that a true vicious circle might be established. It is easy to imagine that this mechanism could be the cause of the over-distension of superficial air sacs, with bulla formation, which occurs in emphysema, although the usual explanation given is that cough distends these air sacs. It is obvious, however, from the mechanism of coughing, which is discussed below, that the lung is compressed rather than distended, and it does not seem possible that cough could be responsible for the formation of bullae, except perhaps in poorly supported areas such as the apex of the lung. Presumably it is this superficial over-distension of air sacs and bulla formation which causes the remarkable hyperresonance of the percussion note—a note which is often more resonant than over a pneumothorax. Why this should occur has not been explained, but it may well be that the over-distended air sac acts as a sound-box or resonating chamber, in the same way as does a cavity. It is also easy to imagine how this distension might occur, more particularly along the edges of the lung, where so-called pleural sinuses exist. With each inspiratory effort on the part of the pectoral muscles the anterior chest wall is pulled outwards and upwards as a whole, and much of this force must be expended on pulling the lung into the pleural

sinuses so as to fill the potential gap between the chest wall and the heart. In time this part of the lung will become over-distended, so that there is a gap between the heart and the chest wall, filled by lung. This space can be clearly seen in the lateral view of a radiograph, and it explains a variety of physical signs. The absence of the apical impulse, loss of cardiac dullness, and distant heart sounds necessarily follow. The expansion of the lung, so that it covers the heart in considerable depth, may also in part account for the increase in antero-posterior diameter and the barrel shape of the chest. Similarly the loss of liver dullness must in part be caused by expansion of the lung into the pleural sinuses, although the low position of the diaphragm is of course another factor.

All these changes can be explained directly or indirectly on the basis of loss of elasticity; but it should not be forgotten that enlargement and deformity of the thorax and its contents are partly dependent on other factors, such as the elasticity and mobility of the thoracic cage. These factors vary with the age and build of the patient, and are presumably responsible for the inconstancy and unreliability of the physical signs of emphysema. There remain several physical signs which have not been discussed or explained. Breath sounds are usually faint, especially at the bases, where they may be inaudible; but as I do not know how vesicular breath sounds are produced in health it is difficult to discuss the reason for their suppression. A possible explanation, held by some Continental writers, is that vesicular breathing is produced by the jet of air thrown into the atrium from the alveolar duct. The absence of this mechanism in emphysema has already been discussed, and may be responsible for the suppression of breath sounds. Vocal resonance and fremitus are sometimes decreased in emphysema. I have no explanation to offer for this, as I do not understand the mechanism of conduction of the spoken voice in the healthy lung, although I know of several theories which do not fit the facts.

There are several factors which may contribute to the formation of the barrel-shaped chest, and, although these are not entirely independent of one another, their relative importance probably varies from patient to patient. I have already described how loss of elasticity contributes two factors towards this change: the first was the inspiratory position of the chest, and the second the expansion of the lung between the heart and the sternum. A third important factor must be the dorsal kyphosis, which is distributed throughout the thoracic vertebrae, and which may produce an increase in the antero-posterior diameter by the same mechanism as in Pott's disease. There are thus at least three separate causes for the deformity of the chest, and another factor must be the diminishing flexibility of the chest wall with advancing age. It is not surprising, therefore, that the barrel-chest phenomenon is variable, being marked in some cases and inconspicuous in others.

Thus loss of elasticity alone could directly or indirectly cause the dyspnoea of emphysema, almost all the physical signs, and a considerable proportion of the morbid anatomical appearances. There are, however, a number of changes characteristic of emphysema which I am unable to explain on the basis of loss of elasticity. These are the destruction and degeneration of alveolar walls and blood vessels, the degeneration and atrophy of the pleura, and the degeneration with loss of elasticity of the costal cartilages and the thoracic vertebral cartilages. All these structures are part of the respiratory apparatus, and it is reasonable to suppose that the cause of this widespread damage is also the cause of the degeneration of the elastic fibres themselves. The nature of this destructive agent is discussed below.

## Aetiology

In seeking the fundamental cause of emphysema I have described the fallacy of thinking in terms of over-distension and overstretching of the lungs. The lungs as a whole are not over-stretched, and we should think rather of some agent which produces destruction and degeneration of many of the structures concerned in respiration, both in the lung and outside it. With this in mind I propose to review briefly the various theories that have been suggested as the cause of emphysema.

The expiratory theory is that the air sacs become over-distended because they cannot be emptied. The inspiratory

\* An abridged version of the Goulstonian Lectures delivered before the Royal College of Physicians on March 4, 9, and 11, 1943.

theory claims that over-distension is produced because too much air is drawn into the lungs by the increased inspiratory effort which precedes coughing and which may be associated with asthma, manual labour, and occupations such as glass-blowing and the blowing of wind instruments. There is also a theory that emphysema is primarily due to a faulty position of the chest and that it is the enlargement of the thoracic cage which causes overstretching of the lung. Many criticisms have been levelled against these three theories, but I will only repeat that, from the evidence already described, all of them appear to be based on the false assumption that the lung as a whole in emphysema is truly overstretched and over-distended.

It has been claimed, from quite unconvincing evidence, that local impairment of nutrition is the cause of emphysema. I have pointed out that under resting conditions there is no diminution in the total amount of blood flowing through the lungs, and it is also true that in other diseases there may be more extensive atherosclerosis than is seen in emphysema, although the lung does not become emphysematous. For these reasons it is improbable that the vascular changes in the lung are of any aetiological significance.

It has been suggested that the lung changes are primarily degenerative or atrophic; but this is too easy a way of evading the issue, as it by no means explains the many aetiological factors known to be involved. The most obvious of these concerns respiratory obstruction. Almost all cases of emphysema have a long-standing history of chronic bronchitis or asthma, or both, and this is also true of emphysema in horses and cattle. The effects of cough and bronchial spasm on the lung, and their mechanism, are therefore of primary importance in any discussion on the aetiology of this disease. The mechanism of coughing is simple. There is a short inspiratory effort which by no means fills the chest to full capacity; the glottis is then closed, and the lungs are forcibly compressed by all the muscles of expiration, so that the pressure of air in the alveoli may rise to over 50 mm. of Hg (Kountz and Alexander, 1934; Rasmussen and Adams, 1942). The glottis is then opened and the strain on the ribs, the pressure on the pleura, and the pressure in the alveoli are suddenly released. In the case of the alveoli there must be a wave of pressure change passing from the bronchi out to the periphery of the lung. It is presumably this sudden release of pressure which is responsible for the sensation, usually experienced, that the lung is being distended. It is obvious, however, from the mechanism of coughing, that the lung is compressed and not in any sense distended. This building up of pressure followed by its sudden release must mean increased stress and strain on all the structures involved, especially on the alveolar walls, which are not robust and through which passes this wave of pressure change. A chronic bronchitic may cough scores of times in a day, and it seems reasonable to suppose that this type of stress and strain, or wear and tear, repeated over many years, could in time produce the loss of elasticity and degenerative changes observed in the alveolar walls. In many respects there is an analogy in hypertension, in which, without any overstretching of the blood vessels, there may be loss of elasticity and other degenerative changes, and these are ascribed by recent investigators to the chronic stress of raised pressure. Outside the lungs it is also reasonable to suppose that wear and tear might occur when cough is chronic. The pleura might suffer for the same reason as the alveoli, and the thoracic cage is also strained: one has only to place a hand over the costal cartilages while coughing to realize that the impact is considerable.

In asthma there may be the same degree of change in intra-alveolar pressure as in coughing, and although the change is not so sudden, it is repeated more often (v. Neergaard and Wirz, 1927; Hartwich, 1930). This stress and strain repeated many thousands of times a day should have the same effect as chronic cough. The mechanism of the experimental production of so-called emphysema by tracheal stenosis in animals is presumably the same (Paine, 1940a, 1940b). It is also true that during an acute attack of bronchial asthma the increased expiratory resistance may lead to distension of the lung, which tends to subside when the attack is over. This temporary distension does not rupture the alveolar walls, or in fact lead to any permanent damage, but it probably does add to the stress and strain produced by the other factors I have described.

Almost all patients with emphysema suffer from either chronic bronchitis or asthma, and in these cases the explanation of the pathogenesis of emphysema which I have given is the most likely one. It is also true that some patients with chronic bronchitis or asthma develop emphysema comparatively rapidly, while others never become emphysematous. The forcefulness of the cough is obviously an important factor, and age is another. To discuss the changes in resistance to wear and tear or to trauma that occur in senescence would in itself occupy several lectures, but no one would dispute that with age there is a decrease in the resistance of the tissues. This is particularly true of the elasticity of the blood vessels; and with advancing years there may also be diminished resistance in the lungs, and in the elastic structures of the thoracic cage, to the stress and strain of cough or of asthma, and this diminution in resistance may take place earlier in some individuals than in others.

There still remains to be explained the unusual case of emphysema with no previous history of asthma or chronic bronchitis. I have seen three such cases when shortness of breath preceded the onset of cough, and in one the diagnosis was confirmed at necropsy. I can only suggest that, very rarely, the stress and strain on the lung which occurs with ordinary breathing may be sufficient to destroy its elasticity.

Other aetiological factors have been suggested, and a hereditary tendency to emphysema is one. This may be so, but I have not seen it except indirectly as a possible familial tendency to asthma and chronic bronchitis. Hard manual labour is another, but my own belief is that this is only of importance in that it increases the incidence of chronic bronchitis and accelerates the process of ageing. It is also a striking testimony to the conservatism of medical teaching that there is scarcely a textbook of medicine which does not quote glass-blowing and the blowing of wind instruments as probable or possible causes of emphysema; and this in spite of ample evidence in the literature that no such aetiological relationship exists (Christie, 1939). The original statement of Laennec, made in 1819, based on no actual cases, has been copied from textbook to textbook over a period of 120 years.

### Diagnosis

I believe it is those with little clinical experience who think they have a clear conception of the diagnosis of emphysema. The pathology of the disease as taught is quite precise and the description of its clinical manifestations is equally so, but the differential diagnosis is not even mentioned in most textbooks. It is those with wide clinical experience who have expressed difficulty in interpreting the so-called physical signs of emphysema. I have discussed the diagnosis of emphysema with many clinicians, and have found a wide divergence of opinion as to the reliable signs of this disease. All were agreed that the physical signs as traditionally described could be of value in diagnosis but could also be misleading. Obliteration of the cardiac dullness, diminished chest expansion, reduction in vital capacity, and the radiograph were each suggested as being most valuable in doubtful cases. I can find no agreement—in fact, there is wide disagreement—with regard to the relationship of the barrel-chest phenomenon to emphysema. Some believe, and teach, that the physical signs associated with the barrel-shaped chest, if definite, necessarily mean emphysema, although they admit that the lesion may neither progress nor lead to symptoms. Others believe that the barrel-chest phenomenon may occur quite independently of emphysema, and that in these circumstances it is of no significance. Such a divergence of opinion as to the diagnostic criteria naturally makes for scepticism, and attempts to correlate the clinical diagnosis of emphysema with the facts as revealed by necropsy have led to further doubts. It has been stated that only a small proportion of those diagnosed at necropsy are recognized during life, and it has also been shown that many of those with barrel-shaped chests furnish no evidence of emphysema when they come to the post-mortem table (Cabot, 1927; Davidson, 1936; Roelsen, 1938). For this reason some writers have gone so far as to say that the physical signs of emphysema are meaningless. I believe that this is certainly untrue, just as I believe that the textbooks are misleading, to say the least, in the neat array of physical signs which they present.

In order to determine the reliability of these physical signs Dr. P. Hill and I have reviewed 72 cases diagnosed on the post-mortem table as generalized hypertrophic emphysema. All of these cases came from the medical wards of the London Hospital, but an accurate and detailed case history was not always available, as some were moribund on admission. A history of chronic cough was given in 94%, and in a quarter of these it was associated with mild or severe asthma. Dyspnoea on exertion was present in 78% of the 45 case histories in which mention was made of the presence or absence of this symptom. In the majority of cases, however, the physical signs of emphysema were not observed. In 35% there was enough evidence to suggest an "emphysematous chest," but in only 13% could this evidence be said to be complete. This series of cases suggests that a more reliable guide to a diagnosis of emphysema than the physical signs is a history of chronic cough or asthma, associated with dyspnoea on exertion. I have therefore investigated another series of 25 patients who gave such a history and in whom no cause of dyspnoea other than emphysema could be discovered. In 92% of them two or more of the physical signs of emphysema were present, and in these a diagnosis of "emphysematous chest" might have been made: in 90% expiration was prolonged, but the incidence of any other individual physical sign was not more than 72%, and only 44% showed the traditional picture of emphysema. The average age of these patients was 54 years, and as a control to this series I have analysed a group of 40 patients, all over the age of 45, none of whom had a history of either cough or dyspnoea. In 9 of them the chest might have been said to be "emphysematous," and 4 presented the classical physical signs of emphysema.

The only conclusion that can be drawn from these series of cases is that the signs of emphysema are unreliable: they may be absent in patients suffering from the disease, and are not uncommonly present in patients without emphysema. Several special diagnostic methods have been recommended; but these are seldom used, and their reliability has not been established. The vital capacity in emphysema is usually diminished. I have made this measurement on 25 cases, all of them with a history of chronic bronchitis and dyspnoea on exertion. In 20 the vital capacity was less than 70% of the normal standard, as calculated from the surface area, and in 13 it was less than 60%. There is a natural tendency during senescence for the vital capacity to diminish; but at any age a vital capacity below 60% of the normal is significant, as is less than 75% of normal before the age of 50.

The diagnostic value of the vital capacity is enhanced if this measurement is made on the type of recording spirometer which is employed in the routine estimation of the basal metabolic rate. Such a record not only gives a measure of the vital capacity but can also be used to indicate the loss of elastic recoil in the emphysematous lung. I have discussed these tests in detail elsewhere (Christie, 1934; Meakins and Christie, 1934): they are based on the fact that when a normal individual takes a deep breath his lungs recoil passively to their original size because of their elasticity. In emphysema this recoil is abolished or impaired, and the lung has to be compressed by the muscles of expiration. After a full inspiration, therefore, the lung is seldom deflated to its original size when the patient is asked to expire forcibly. There are two other manifestations of loss of elasticity which can be demonstrated by this type of respiratory tracing: after a full inspiration the patient is incapable of deflating his lung as efficiently as after an inspiration of moderate depth, and the level at which the patient breathes is irregular.

During the past ten years I have performed this test on 66 patients with chronic bronchitis and dyspnoea on exertion: in 30 these characteristics were obvious and constant, in 26 the tracings were suggestive of loss of elastic recoil, and in the remaining 10 no abnormality could be detected. Of 116 controls, 11 would not co-operate, none showed definite loss of elasticity, and only 4 were suggestive of slight loss of elasticity. The main value of these respiratory tracings is that it is only patients with emphysema who consistently show loss of elastic recoil: admittedly this is true of only about 50% of cases, but most of the others give tracings which are suggestive. The drawbacks of this test are obvious. Except in hospitals where

the basal metabolic rate is measured by means of a recording spirometer, special equipment is required. The test has to be performed by someone with special knowledge of respiratory tracings, patience is required to ensure that the subject knows what is wanted of him, and I do not expect that this test will be used except perhaps by those who have a particular interest in emphysema.

It is easier to measure the chest expansion than the vital capacity, but unfortunately this also diminishes with age. In my experience about 60% of patients with emphysema have a chest expansion of less than one inch, but I have seen it reduced to half an inch in a man aged 63 in whom there was no other evidence to suggest pulmonary or cardiovascular disease.

In recent years the radiograph has been suggested as a reliable guide to emphysema. This has not been my experience. In 11 cases in which the diagnosis was confirmed at necropsy, radiographs suggested emphysema in only 5. In 25 other cases, in which diagnosis was made on clinical grounds, the value of the x-ray film was approximately the same.

A diagnosis of emphysema based only on physical signs is therefore unreliable, since these depend largely on the barrel-chest phenomenon, which may occur independently of this disease. In my opinion the diagnosis should only be considered certain when dyspnoea on exertion, of insidious onset, not due to bronchospasm or left ventricular failure, appears in a patient who has some of the physical signs of emphysema together with chronic bronchitis or asthma. The absence either of dyspnoea or of physical signs should cast doubt on the diagnosis, but should not exclude it; the more physical signs present in a patient with chronic bronchitis or asthma, the greater is the likelihood that he has emphysema. I must confess, however, that in the absence of dyspnoea I am always uncertain as to diagnosis and prognosis, but when dyspnoea of the type described above appears in a patient with chronic bronchitis I am very seldom in doubt. A large series of cases will have to be followed up over many years before the necessary criteria for early diagnosis can be established. Until this has been done I feel that the terms "emphysematous" and "emphysematous chest" should be discarded, as it is their use which has been partly responsible for the lack of progress in the understanding of emphysema since its classical description over a century ago by Laennec. These terms are quite misleading, and should be replaced by some such expression as "barrel chest" or "barrel-chest phenomenon," reserving the diagnosis of emphysema for those patients who have the symptoms as well as the signs of the disease. I feel that if this were done the chances of progress would be increased, particularly with regard to the use of special diagnostic procedures.

### Treatment

The treatment of emphysema is essentially symptomatic, as elastic tissue cannot regenerate and nothing can restore the structure of the lungs. Until heart failure supervenes, the only symptom, other than cough, is dyspnoea on exertion, and I will first emphasize the value of ephedrine. Although there may be no evidence of bronchospasm or resistance to respiration, the administration of ephedrine not infrequently relieves the dyspnoea of emphysema. A possible explanation of this effect is that the bronchioles leading to the over-distended air sacs and bullae are less capable of changes in calibre than those leading to healthier parts of the lung; bronchospasm, although not clinically manifest, would in this case increase the proportion of the inspired air deflected to these useless parts of the lung, and the relief of bronchospasm with ephedrine would improve the efficiency of ventilation and thus relieve dyspnoea.

Several procedures, the purpose of which is to deflate the lung, have been described, and it is said that these increase the efficiency of respiration. Pneumothorax is one, and relief of dyspnoea from this procedure, both in man and in horses suffering from this disease, has been claimed. More popular in this country, and less dangerous, are respiratory exercises designed to teach the patient to deflate the lung and to increase the use of the diaphragm. A well-fitting abdominal belt will also raise the diaphragm by increasing intra-abdominal pressure, and, more recently, pneumoperitoneum has been suggested for the same purpose. All these procedures have been recom-

mended, and various theories have been put forward to explain the beneficial effects observed. Two effects are common to most of them. First, the diaphragm is raised so that its convexity is increased and its efficiency therefore enhanced, and it was for this purpose that I first suggested the use of the abdominal belt. Secondly, the lung is deflated by these procedures so that it contains less air. The decrease in volume is, however, very small—so small that it can hardly be measured—and the beneficial effects are probably for the most part due to increased efficiency of the respiratory musculature. It is also possible that with greater collapse of the superficial bullae efficiency of ventilation may be increased.

When heart failure supervenes oxygen should be given, as the added insult of anoxia to a heart that is failing for other reasons greatly lessens the chances of recovery. Recovery from heart failure in emphysema is uncommon, but I have recently had a patient who recovered from two attacks, during both of which he was moribund. In the first oxygen was administered continuously for one week, and in the second for 10 days. He subsequently died during a third attack, and the diagnosis of emphysema was confirmed at necropsy.

The treatment of emphysema is thus far from being hopeless, although it is essentially symptomatic. Ephedrine should be tried in all cases. Respiratory exercises or an abdominal belt, or both, may increase considerably the tolerance to exercise. And lastly, when heart failure supervenes oxygen therapy is of the greatest value.

### Summary

In this paper the disturbance of function in emphysema, and its mechanism as revealed by experiment at the bedside, are emphasized, and the bearing of these clinical observations on the natural history of the disease and its diagnosis is discussed. The primary lesion is loss of elasticity, the most common cause of which is the stress and strain of cough or respiratory obstruction on the structures concerned in respiration, the process being comparable to the loss of elasticity which occurs in blood vessels following hypertension. Almost all the symptoms and signs of emphysema, and also the over-distension of air sacs and formation of bullae, can be explained on the basis of loss of elasticity, and it is suggested that it is the wastage of ventilation on this "pathological dead space" which is responsible for the dyspnoea and the impairment of haemo-respiratory exchange which occur. The difficulties and fallacies in the diagnosis of emphysema are described, and it is suggested that the present state of confusion would be diminished if the diagnosis were reserved for those who have symptoms as well as signs of this disease.

The Trustees of the Nuffield Provincial Hospitals Trust have set aside a substantial sum for grants towards the establishment of preliminary training schools for nurses for the benefit of groups of hospitals, both voluntary and municipal. Schemes will be considered from Regional and Divisional Hospitals Councils or other joint hospital bodies recognized by the Trust. For areas in which these bodies do not exist, the Trustees have agreed to receive schemes through the appropriate area committee of the British Hospitals Association, but they must cover facilities for local authority as well as voluntary hospitals.

## INFANT FEEDING IN RELATION TO MORTALITY IN THE CITY OF BELFAST

BY

JAMES DEENY, M.D., M.Sc., F.R.C.P.I.

AND

ERIC T. MURDOCK, B.Sc., Ph.D., A.I.C.

(Lurgan)

In the course of a recent study of the infant mortality problem in Belfast we have collected some facts relating to infant feeding. For this city the death rate of children under 1 year has been high, and during the past four years has ranged from 85 to 122 per thousand live births. In the survey data were obtained concerning 554 deaths, or 84% of the total deaths of legitimate infants occurring from June, 1941, to June, 1942, in Belfast (completed by Dec., 1942). The total legitimate births in Belfast for this period were 7,778, 3,359 occurring in the first six months. Material was also collected from a group of children who had survived 1 year of life in the city. This control sample was established by selecting every fifth child born during the first six months of the period, and, allowing for wastage, finally numbered 477.

In order to maintain constant values the information was obtained by one investigator (E. T. M.) from a personal visit to the parent or guardian. Parents usually possess vivid memories of the circumstances of the death of their children, and were generally willing to discuss the matter. Cases were excluded when the fatal illness was due to hardships resulting from previous air raids, and when families had moved from the city and could not be followed up. Information was recorded concerning the size of the family (and previous infant deaths), income, housing, the care and feeding of the child, domestic hygiene, the ante-natal and obstetric attention, cause of death, the medical, nursing, hospital, and other factors relating to the fatal illness—entailing more than 40 questions in each case. In the control group somewhat similar data were obtained. This paper deals only with the information we have secured concerning infant feeding.

### Infant Feeding in Belfast

Feeding is an important factor associated with infant mortality, and in any examination of the problem a knowledge of the general character of the infant feeding practised is necessary. This subject was considered under three main headings—viz.: (1) the principal foods given to ordinary children for the first six months of life; (2) the food given for the second six months; and (3) foods the infants received before the fatal illness. It is obvious that this method of inquiry does not yield results in great detail, but it will present a fairly accurate picture of the main methods of infant feeding used in the city.

TABLE 1.—Analysis of Feeding of Infants in the Control Group, during the First Year of Life

Method of Feeding	Aged 0-6 months	Aged 6-12 months
Breast-fed (with or without "supplement")	337 (71%)	157 (33%)
Cow's milk	61 (13%)	33 (7%)
Dried proprietary milk	40 (8%)	19 (4%)
Cereal foods	39 (8%)	58 (12%)
Cereal and "mixed feeding"	—	68 (14%)
"Mixed feeding" and cow's milk	—	142 (30%)
Total	477 (100%)	477 (100%)

For the children in the control group, which is representative of living children in Belfast, we found (see Table 1):

1. During the first six months almost three-quarters received breast milk, with or without a "supplement," as the principal food. Of the remainder, a slightly larger proportion were fed on cow's milk than on cereals or dried proprietary milk.

2. During the second six months the same children showed a change in diet, with a decrease in breast-feeding. Only one:

third received breast milk, another third were given "mixed feeding" and cow's milk, and the remainder were fed on such diets as cow's milk alone, dried proprietary milk, or cereal foods with or without "mixed feeding."

3. *The major feeding before the fatal illness* was studied in the mortality group, as we thought that this would give most information on the relation of feeding to mortality. From this, and by relating the figures obtained to the age at death (Table II), it was found that the feeding followed the general

TABLE II.—*The Major Feed before the Fatal Illness Classified according to Age at Death*

Feeding before Fatal Illness	Age at Death						Total
	Under 7 days	1-4 wks	4 wks-2 mths	2-5 mths	5-6 mths	6-12 mths	
Breast-fed (with or without "supplement")	2	2	29	21	23	24	126
Cow's milk	—	5	20	23	47	36	131
Dried proprietary milk	1	7	6	9	26	20	74
Cereal foods	—	—	—	4	12	20	38
Other methods	—	—	1	—	—	1	2
Total	3	41	56	57	108	106	371
Congenital or premature cases not affected by feeding	133	44	6	—	—	—	183
Total	136	85	62	57	108	106	554

trends experienced in such groups—i.e., the amount of breast-feeding diminished as age increased, with a correspondingly greater use of the other foodstuffs. Age of death seemed to be the major factor influencing the manner of feeding before the fatal illness.

#### Incidence of Breast-feeding

Nowadays so many babies receive supplements that it was thought advisable to use a broader definition of breast-feeding. Consequently, in the following consideration of the duration of breast-feeding the infant was classified as breast-fed if the major part of its diet was breast milk.

It is apparent that there is a substantial difference in the extent of breast-feeding between the mortality and control groups (Tables I and II). These findings cannot be directly compared, as the same aspects of feeding were not considered in the two groups. However, figures giving a simple comparison can be obtained from our data by determining the percentage of babies breast-fed at various ages. In the mortality group the percentage breast-fed was based on the number of infants alive at these ages, and was found by relating the duration of breast-feeding to the age at death as in Table III. This table also gives the duration of breast-

TABLE III.—*Number of Infants who Died classified according to Duration of Breast-feeding and Age at Death, and Number of Infants who Survived (Control Group) classified by Duration of Breast-feeding*

	Mortality Group (Dead Children)							Control Group (Living Children)	
	Age at Death								
	Under 1 day	1-7 days	1-4 wks.	4 wks., 2 mths.	2-3 mths.	3-6 mths.	6-12 mths.		Total Deaths
Unsuccessful attempt to estab- lish breast-feeding	—	9	6	1	—	5	4	25	14
Died before breast-feeding could be established	67	27	—	—	—	—	—	94	—
Not breast-fed	—	19	40	21	23	22	18	143	30
Breast-fed for:									
Less than 1 month	—	14	39	11	9	26	22	121	74
1 mth. but less than 2 mths.	—	—	—	29	7	17	7	70	35
2 " " "	—	—	—	—	18	11	3	32	33
3 " " "	—	—	—	—	—	27	18	45	50
4 " " "	—	—	—	—	—	—	—	50	56
5 " " "	—	—	—	—	—	—	—	—	—
6 " " "	—	—	—	—	—	—	—	—	—
9 months and over	—	—	—	—	—	—	—	—	—
Total	67	69	85	62	57	108	106	554	477

feeding for the control group. At 1 month of age three-quarters of the children in the control group were breast-fed. Of the infants in the mortality group, at 1 month only one-half were breast-fed—a striking contrast. The proportion breast-fed is considerably less at each month of age in the mortality group

than in the control group (Table IV). Despite the smallness of the numbers in the sample this conclusion is decisive.

TABLE IV.—*Comparative Incidence of Breast-feeding in Infants who Died and in those who Lived*

Age of Child in Months	Numbers Living		Numbers Breast-fed		Percentages Breast-fed	
	Mortality Group	Control Group	"M" Group	"C" Group	"M" Group	"C" Group
1	333	477	171	359	51	75
2	271	477	101	324	37	68
3	214	477	70	289	33	61
6	106	477	24	206	23	43
9	—	477	—	156	—	33

Duration of the fatal illness of infants in the mortality group does not account for a significant part of the difference between the mortality and control percentages of breast-feeding at each age; a special analysis shows that of the 333 in the mortality group who survived one month, 60% of whom 40% were breast-fed—were sick at this age, leaving 273 who were still healthy. Of the latter, the number breast-fed was 147, or 54% of the total not sick. Thus the omission of sick children from the mortality group only increases the percentage of breast-fed babies from 51 to 54, and this is still very significantly different from the 75% of breast-fed observed in the controls.

#### Social Factors and Incidence of Breast-feeding

The possible influence of some social factors as a cause of the marked disparity between the incidence of breast-feeding in the mortality and that in the control group was studied: income, housing, and domestic hygiene were considered.

*Income* in relation to breast-feeding was analysed by dividing the infants of both groups into three different income grades. These were based on the amount, less rent, available to the mother for household purposes per head (including the child in question) per week. In the mortality group the amount reckoned was the weekly average for the month preceding the fatal illness. A similar average when the children were 6 months old was taken in the control group. The proportion of infants breast-fed in each income level, at various ages, was determined for the mortality and control groups, and the results show that the variations in income considered did not affect the measure of breast-feeding in either group.

*Housing*.—In ascertaining the effect of housing, the infants of the two groups were arranged in classes according to the number of persons per room in each house, and the proportion of children breast-fed in each class found.

*Domestic Hygiene*.—The influence of domestic hygiene was considered by dividing the homes of the infants into three grades: (A) very clean and showing maternal efficiency; (C) dirty or showing maternal inefficiency; (B) intermediate conditions. These analyses (Table V) show plainly that changing values in housing or domestic hygiene did not appreciably influence breast-feeding.

#### Order of Birth and Other Factors

*Order of Birth*.—This has an important effect on infant mortality, and on this account the possibility of a relationship between birth order and breast-feeding was examined. The infants in the mortality and control groups were classed according to this factor, and the incidence of breast-feeding determined in the classes for the various ages. While the figures obtained (Table V) may indicate vague trends relating breast-feeding incidence and birth order, statistical treatment shows that these tendencies are not significant for the numbers involved.

*Cause of Death*.—The incidence of breast-feeding was considered in respect of the following three causes: (a) gastro-enteritis; (b) respiratory infections; and (c) other causes. "Other causes" include prematurity and injury at birth—from the latter group only eight babies dying survived one month. The slightly lower incidence of breast-feeding among infants dying from gastro-enteritis (Table V) is not statistically significant, and could be ascribed to chance variation.

*Occupation*.—As very few of the mothers were engaged in industry this factor was neglected. Any attempt to establish vocational grades based on the occupation of the father failed owing to the number serving in the Forces.

The age of the mother was not sought. It was considered that the numbers in the samples would not be sufficient to give a satisfactory analysis for the necessary age groups. (See Campbell, 1929; Burns, 1942.)

#### Statistical Note

In Table V the figures relating the factors to the incidence of breast-feeding at 1 month and at 2 months of age are given. Results at 3 and 6 months furnish the same conclusions, but are not included in the table. A number of "sorts" for each social factor were

Of the former 51% were breast-fed at one month, while 75% of the latter were breast-fed at that age. This result is in agreement with the finding of Grulee *et al.* (1934) that the infant mortality rate is much higher in artificially fed children.

Our results show that the social factors of income, housing, and domestic hygiene have no significant influence in determining the extent of breast-feeding in either the mortality or the control group. This endorses the biological nature of the process of breast-feeding. The investigation of the effect of order of birth or cause of death on breast-feeding revealed

TABLE V.—Incidence of Breast-feeding at Ages of 1 Month and 2 Months related to Various Factors

		1 Month				2 Months			
		Numbers Breast-fed		Percentages Breast-fed		Numbers Breast-fed		Percentages Breast-fed	
		Mortality Group	Control Group	"M" Group	"C" Group	"M" Group	"C" Group	"M" Group	"C" Group
(i) Income less rent per head per week	Under 10s. . . . .	75	85	61	77	51	74	43	67
	10s. and under 15s. . . .	52	118	65	75	27	114	35	72
	15s. and over . . . . .	44	156	48	75	23	136	31	65
(ii) Housing: Number of persons per room (including the child in question)	Less than 1 . . . . .	30	96	62	75	14	85	37	66
	1 but less than 1½ . . . .	57	158	47	77	34	142	33	69
	1½ and including 2 . . . .	38	67	49	77	24	63	39	72
	More than 2 . . . . .	46	38	53	68	29	34	43	61
(iii) Domestic hygiene	Condition A . . . . .	56	165	47	76	29	150	31	69
	Condition B . . . . .	86	157	65	75	51	140	41	67
	Condition C . . . . .	29	37	48	71	21	34	40	65
(iv) Order of birth	First births . . . . .	55	133	56	73	33	118	43	64
	Second births . . . . .	28	69	49	71	14	61	29	63
	Third births . . . . .	30	51	48	82	16	46	30	74
	Fourth and fifth births . . .	22	58	46	82	13	55	33	77
	Sixth births and others . . .	36	48	54	75	25	44	45	69
(v) Cause of death	Diarrhoea and enteritis . . .	44	—	48	—	25	—	33	—
	Respiratory infections . . .	63	—	55	—	41	—	39	—
	Other causes . . . . .	63	—	52	—	35	—	38	—

involved in calculating these figures. The standards of the social factor were related (a) to the age at which breast-feeding ceased, and (b) to the age at death. From analysis *a* the number of children in the standard classes of the social factor at each month of age was determined, and analysis *b* gave the total number of children alive in the standard classes at these ages for the mortality group.

The significance of the figures in this table was tested by a  $\chi^2$  analysis. All differences from the expected figures for a "no relationship" consideration may be ascribed to chance. For each analysis, *P* is greater than 0.3—except in the case of birth order in the control group, when, with  $\chi^2 = 11.8$  and  $n = 8$ , *P* is between 0.2 and 0.1.

#### Comment

In the first part of this paper it has been shown that three-quarters of the children who had survived one year in Belfast were principally breast-fed, with or without a supplement, during the first six months of life. Of the small numbers of these children not breast-fed less than one-third were fed on cereal foods—the remainder received dried proprietary milk or cow's milk. For the larger part of the second six months one-third were breast-fed. This analysis of the feeding methods employed takes into account only the nature of that feeding. Such important considerations as the quality, quantity, or nutritive value of the foods could not be examined. Assessing the feeding practised in the city by the prevalence of breast-feeding or by the nature of the artificial foods given, the infant feeding in general use can be considered as adequate. This conclusion is supported by the finding, previously reported, that the incidence of gastro-intestinal and respiratory infections in the control group is low, although these two diseases are the cause of 42% of the deaths in the mortality group (Deeny and Murdock, 1943).

Even if the wider definition of breast-feeding employed in this study is taken into account the figures obtained for the control group show an incidence of breast-feeding in Belfast comparable to that of similar groups in other cities with a lower infant mortality rate. In addition a greater proportion of infants are breast-fed for a longer time (Blessing, 1937; Spence, 1938; Robinson, 1939; Hughes, 1942).

The study reveals a marked difference in the incidence of breast-feeding between the infants who die and those who live.

no appreciable relation. The consistency of these findings is noteworthy. No statistical relationship could be demonstrated throughout the subdivisions of each factor considered, either in the mortality or in the control group.

From the data it has not been possible to determine any further relation between the incidence of breast-feeding and mortality than that shown. However, it is interesting to consider the significance of this lowered incidence of breast-feeding in the mortality group. Would an increase of breast-feeding in this group reduce the mortality rate appreciably? We suggest that it would not, and that this lowered incidence of breast-feeding should be regarded more as an effect than as a cause of unsuccessful reproduction.

#### Summary

Facts concerning infant feeding obtained in a study of 554 deaths (84% of the total) occurring in one year in Belfast, and in a control group of 477 living infants, are presented.

The extent of breast-feeding in the infants who died was much less than in the control group.

The factors of income, housing, domestic hygiene, order of birth, and cause of death are shown to have no appreciable influence on the extent of breast-feeding in Belfast.

A statistical treatment of the results is given.

This work is a portion of a study of the infant mortality problem in Belfast which is being presented to the Statistical and Social Inquiry Society of Ireland. We wish to thank the Medical Research Council of Ireland for its generous assistance. We are grateful to the Director, the Senior Statistician, and Staff of the Statistical Branch of the Department of Industry and Commerce, Eire, for machine compilation of the data and technical advice, and appreciate their courtesy and kindness.

## AN UNUSUAL CASE OF CEREBRAL MALARIA

BY

CHARLES S. D. DON, M.D., M.R.C.P.

Temp. Major, R.A.M.C.; Medical Specialist

AND

P. F. MEYER, M.D.

Captain, R.A.M.C.; Graded Physician

This case is reported because of the large number of parasites in the blood film and the severe clinical signs, in spite of which recovery followed.

## Clinical History

The patient, a soldier aged 22, was admitted to a C.C.S. in North Africa on July 10, 1943. We subsequently learnt that while on local leave in North Africa he became ill, but attributed the illness to the heat and did not consult a medical officer. He had no clear memory of how he reached this C.C.S.; he last remembers travelling in a train with other soldiers, who finally took him to the central M.I. room of this area.

He was admitted late at night, about five or six days after the onset of the illness. On examination he complained of headache and vomiting. He was drowsy but not unconscious, and could answer questions reasonably well. The temperature was 102.4° F. The spleen was easily palpable. The urine was of normal colour. Blood slides showed a very heavy malarial infection. The thick film was crowded with parasites. Examination of the central parts and the edges of the thin film revealed that, on an average, 35% of the red cells contained parasites. Of the infected cells 82% had one ring, 17% had two rings, and 1% had three or four rings per cell. Several crescents of *Plasmodium falciparum* were also seen.

He was given 10 gr. of quinine dihydrochloride in 20 c.c. of water intravenously and 12 gr. by mouth at 11.30 p.m., the latter dose being repeated in six hours. Next day his condition was only fairly satisfactory; he was still drowsy, but he took 10 gr. of quinine six-hourly by mouth without vomiting. The temperature remained normal all day. A blood film showed large numbers of parasites to be still present. He took fluids fairly well, but passed only very small amounts of urine.

Early on the morning of July 12 the patient was found to be quite unconscious, cold, and collapsed. The tongue was hard and dry. The temperature was 97° F., the blood pressure 80/60, and the pulse 90 per minute. Hiccup was present, and breathing was shallow. As the patient appeared to be dying he was given an immediate injection of nikethamide (coramine). No urine had been passed since the previous night and the bladder appeared to be empty, but when a catheter was passed an ounce of urine was obtained which contained albumin but no blood. Microscopically, granular and hyaline casts were seen. A glucose-saline drip was put up, and by this route he was given in the course of the day 30 gr. of quinine dihydrochloride and two blood transfusions, each of 500 c.c., without a reaction of any kind. The patient was Group B, and each donor was of this group. The serum and red cells of the patient and of each donor were cross-matched and the results read microscopically at the end of one hour. A blood film of the patient showed large numbers of parasites to be still present. The haemoglobin before the transfusion was 70% (Sahli). By evening his condition had improved; the B.P. had risen to 105/80, and the temperature was 101° F. No urine was passed that day.

The following morning—July 13—the patient was semiconscious, and was able to take fluids by the mouth. The temperature was normal, the conjunctivae showed slight jaundice, and a specimen of urine voluntarily passed was typical of that seen in blackwater fever. Spectroscopic examination revealed the presence of oxyhaemoglobin. No red cells were seen in the centrifugized deposit, but granular and hyaline casts were present. While the compatibility of the transfused blood appears to have been established by indirect grouping and careful direct cross-matching, the possibility remains that the haemolysis observed was not due to quinine but to antibodies in the recipient's blood which could not be detected by the methods at our disposal. There was no history of any previous blood transfusion. The intravenous drip was continued; no further quinine was prescribed, and the patient was given by mouth one drachm of sodium bicarbonate hourly to alkalize the urine rapidly. In the course of the day he was given two intramuscular injections of mepacrine methanesulphonate (atebrin musonate), each of 0.1 g., and the urine gradually returned to a normal colour. At 6 p.m. the temperature was 103.6° F.; he was given mepacrine hydrochloride (atebrin) 0.1 g. by mouth, and this was repeated in 6 hours. At 9 p.m. the temperature, which had been taken hourly, had risen to 106° F., and the patient, after having remained semiconscious all day, became delirious and restless. Cold sponges were given half-hourly until 11 p.m., when the temperature had fallen to 102° F.

The intravenous drip was stopped, as oedema of the sacrum was found to be present; he was passing urine freely.

On July 14 the patient's general condition was much improved; for the first time he was quite conscious and rational. The morning temperature was 98° F. A blood film showed no parasites; the red cells exhibited a marked degree of macrocytosis, and megaloblasts were present. The urine still contained albumin and casts. Mepacrine hydrochloride was continued in a dosage of 0.1 g. i.d.s. That evening the temperature rose to 104.8° F.

On July 15 his general condition was better, but he was found to have thrombophlebitis of the left axillary vein (this arm was used for the drip) with oedema of the forearm and hand. The morning temperature, which so far had always been normal, was 100.4° F.

Temperature chart of the case.

There were rales over the lower lobes of both lungs but no dullness. It was decided that he had a hypostatic pneumonia, and was put on sulphadiazine 1 g. four-hourly. The temperature reached 102° and 101° F. on the next two nights, and thereafter settled, remaining normal all day on July 21. By this time the lung signs had disappeared.

## Summary

A case of cerebral malaria is reported in which 35% of the red cells were infected by one or more parasites of *Plasmodium falciparum*.

The most-pronounced cerebral symptoms came on after the patient had been on large doses of quinine for 36 hours.

Transient haemoglobinuria followed 30 gr. of intravenous quinine and two blood transfusions.

Hyperpyrexia was found to be developing after three days of intensive quinine treatment.

Hypostatic pneumonia complicated recovery.

We wish to thank Major-Gen. E. M. Cowell, the D.M.S., North African Force, for permission to submit this report for publication.

## EFFECTS ON RATS OF PROLONGED FEEDING WITH THE STAPLE AFRICAN DIET

BY

JOSEPH GILLMAN, D.Sc., M.B.

(From the Department of Anatomy, University of the Witwatersrand, Johannesburg)

It is known from numerous surveys and observations that pulmonary tuberculosis and other diseases of the respiratory tract are especially prevalent among the Africans (South African negroes). It is also common knowledge that cirrhosis of the liver and especially primary cancer of the liver are very often encountered in this people. In an extensive investigation into the incidence of cancer in South Africa, Berman (1940, 1941) has shown that in a series of 253 cases of cancer of all organs in adult male Africans working in the Witwatersrand gold mines no fewer than 222, or 90%, were primary in the liver. This remarkable state of affairs is even more strongly emphasized when it is remembered that liver cancer is the rarest neoplasm in Europeans.

Several factors are regarded as contributory to this high incidence of cancer, one of which is cirrhosis, which is almost invariably associated with liver cancer. There is a considerable body of opinion which regards this susceptibility to liver cancer

in the pigmented peoples as due to some racial factor. Des Ligneris (1940) has shown that extracts from the cancerous and non-cancerous livers of Africans are capable of producing neoplasms of the skin when painted on the backs of mice. The extracts from normal Europeans are said to be less potent in this respect. A similar experience has been reported by Hieger (1940).

### Effect of African Diet on Rats

Malnutrition among the Africans is widespread in South Africa. The overwhelming majority feed on a diet consisting largely of maize meal (mealie pap) and sour milk. This forms the staple from the time of weaning throughout life. Before invoking a racial or a genetic factor in modifying the incidence of disease it seemed highly desirable to ascertain the effect of the African diet on normal animals. Accordingly 125 rats weighing from 40 to 50 g. were fed exclusively on mealie-meal porridge and sour milk. The mealie-meal porridge was concentrated to form a solid mass, while the sour milk was prepared from fresh milk allowed to ferment in a warm room. The animals received liberal amounts of this food. Apart from thinning of the hair over the abdomen and hind legs and roughening of the tail, no obvious signs of acute avitaminosis were recognized.

After 14 months 12 rats were killed and a full post-mortem examination was performed. The others are being studied biochemically. In all of those killed some degree of liver pathology was evident macroscopically. This varied from diffuse enlargement of the whole liver with obvious fatty change to a widespread nodular cirrhosis, the latter usually involving the left side of the liver. In one case there was complete atrophy of the left lobe, with enormous compensatory hypertrophy of the right lobe—so much so that the enlarged lobe extended almost into the pelvis. In this instance the remains of the left lobe could be seen as two small appendages of cirrhotic tissue.

In this series of rats it seemed that the liver first enlarged and underwent fatty changes and later cirrhosis supervened, or else complete atrophy of the affected lobes occurred, with corresponding enlargement of the right side. The heart was grossly enlarged, and in 9 cases one or both lungs showed recent or old-standing inflammatory lesions with areas of bronchiectasis or abscess formation. The fat in the mesentery, retroperitoneal, or subcutaneous regions was abundant. The skull was very much thickened, especially in the occipital region. The suture lines could be readily identified by the zones of great vascularity. The upper incisor teeth were particularly affected; many of them were broken, some fused, and others loose. The pituitary was enlarged, the thyroids were atrophied, and the suprarenals were small and of greyish colour. In four cases the lymph glands of the peri-oesophageal region and above the lesser curvature of the stomach or above the abdominal aorta were of dark-brown colour, due to the presence of haemosiderin. The jejunum in those cases of advanced cirrhosis contained a dark viscid material which gave the reaction of blood. It is noteworthy that although many thousands of rats were examined post mortem over a number of years no lesions in the liver of the kind described above were ever observed.

### Comment

The significant features of this feeding experiment in rats are the gross pathology in the liver, the frequency of lung lesions, the enlarged heart, the abundance of adipose tissue, the thickened skull, and the dental affections, all of which occurred without any recognizable manifestations of acute vitamin deficiency.

The production of liver damage by means of a diet which forms the staple of the overwhelming number of Africans in South Africa is not without its sociological implications. It may also have repercussions in other parts of the world where economically impoverished individuals are forced to live on a diet similar to that of the African in the Union of South Africa.

This investigation was carried out in the Department of Anatomy, and all facilities were generously provided by the University of the Witwatersrand, Johannesburg. This and subsequent aspects of the problem represent, and will represent, the collaborative efforts

especially of Dr. Leon Golberg of the South African Institute for Medical Research, and of Christine Gilbert, Dr. Theodore Gillman, Joyce de Bruijne, Marianne Cassirer, and Joel Mandelstam of the Department of Anatomy. The work is proceeding actively to discover the factors responsible for the lesions produced experimentally in the rat.

## Medical Memoranda

### Periarthritis Nodosa diagnosed Clinically

Following on the annotation on periarthritis nodosa published in the *British Medical Journal* of May 15, 1943 (p. 608), this case record may be of interest.

### CASE HISTORY

A woman aged 34 was admitted to the Meath Hospital under my care in June, 1942, complaining of "asthma" for the past week. Previous to this attack she had never suffered from asthma or bronchitis or from any other serious illness. On admission her temperature was normal and her pulse rate 118. There was evidence of acute bronchitis, but otherwise physical examination revealed nothing abnormal. A chest radiograph was negative. The urine contained some albumin on admission, but no casts at any time. Investigation for protein sensitivity to foods, flowers, and animal emanations was negative. During her stay in hospital her temperature was occasionally slightly elevated, and her pulse rate after the first week settled down to 80. After a period of five weeks in hospital, during which time she was treated on general lines, the patient went home feeling fairly well.

In Sept., 1942, she began to have further attacks of asthma, for which she was treated with a stock vaccine by her general practitioner, who stated, however, that even a small dose of the vaccine often gave her quite a severe general reaction; and finally the treatment had to be abandoned. Shortly after this she got a thrombosis of the right long saphenous vein, which gave rise to fever at night-time. She recovered completely from the thrombosis, but in Nov., 1942, started to complain of extreme general weakness and malaise and a raised evening temperature. A blood culture done at this time was reported to contain *B. proteus*, but this was considered to be a skin infection. Owing to the presence of petechial haemorrhages on the chest and back, a blood examination was also carried out, with the following results: R.B.C., 4,100,000 per c.mm.; W.B.C., 26,000 per c.mm.; Hb, 65%; colour index, 0.8; platelets, 110,000 per c.mm. Differential count: polymorphonuclear leucocytes 85%, lymphocytes 12%, large mononuclears 3%. Prothrombin clotting time, 35 seconds.

The patient was readmitted to hospital with a temperature of 99° and a pulse rate of 96. On examination this time, in addition to her chest condition she had a very loud grating to-and-fro pericardial friction rub, heard all over the precordium, but the heart sounds underneath did not appear to be altered. There was abundant albumin in her urine, and a catheter specimen revealed pus, red cells, and granular and hyaline casts. Her blood urea was 36 mg. per 100 c.cm. She was put on a nephritic diet. During the first week her temperature rose until it touched 103°, and her pulse rate became elevated to 120. At this stage she was treated with sulphathiazole (0.5 g. q.q.h.), but this gave rise to severe vomiting within the first 24 hours, and was discontinued. A second blood culture done a week after admission grew a staphylococcus—possibly also a skin infection—but the patient was started immediately on large doses of sulphadiazine, and during the next three weeks she received two courses each consisting of 25 g. Repeated white cell counts were done to check sulphonamide treatment; in the course of these a leucocytosis of 42,000 per c.mm. was recorded, with an eosinophilia of 9%. A fortnight or so after admission all signs of pericarditis had gradually disappeared. During her second period in hospital the patient had several attacks of asthma. At times also transitory painful lumps of about the size of a grain of rice appeared on her scalp and eyelids, and remained for about three days. In the middle of December she developed an angioneurotic oedema of the right arm. A little later there was a definite ulnar neuritis of this arm. Throughout her stay her urine was loaded with albumin, and casts were always present—granular, hyaline, and fatty. Her blood urea at all times remained within normal limits. She was discharged at the end of February at her own request.

Shortly after her return home she developed oedema of the legs, which gradually became a generalized oedema associated with ascites. During this time her urine on boiling became almost solid with albumin. In April, 1943, she had painful subcuticular lumps of about the size of a rice grain on the anterior surface of her forearms. Bullae then developed around each lump, and after from four to five days these burst, leaving punched-out crater-like ulcers with bluish-purple margins. At the same time the fingers, especially those corresponding to the ulnar distribution of the right hand, became blue, and dry gangrene ensued. The toes also became blue, but to a less degree. The patient's condition thereafter deteriorated rapidly until, about three weeks before death, the ulcers had coalesced to

form deep gangrenous excavations between the bones of the forearm, in which muscular aponeuroses could be seen. She required a great deal of omopon during the terminal stage of her illness to combat pain. On May 18, 1943, she died.

A post-mortem examination was unfortunately out of the question, and pathological confirmation is therefore lacking, but from the clinical course of the disease I think there is little doubt as to its true nature. Alternative diagnoses of rheumatic pericarditis, acute nephritis, septicaemia, and subacute bacterial endocarditis were all considered in turn as various signs arose, but none appeared entirely to satisfy the symptomatology. The appearance of nodules and the extensive patches of gangrene on the arms, together with the obvious signs of a vascular lesion of the extremities, suggested the true diagnosis.

I am grateful to many for their help in this case, but particularly to Dr. W. O'Donnell, Prof. W. J. E. Jessop, and the late Prof. W. Boxwell, as well as to my house-physicians.

Dublin.

CYRIL MURPHY, M.D., F.R.C.P.I.

### Tetanus following Appendicectomy

The following case seems to be worth reporting because it developed after an operation and was successfully treated without opening up the wound.

The patient was a well-built man aged 29, employed in the N.F.S. For two weeks before admission to hospital he had been complaining of pain and paraesthesia in the finger-tips of the right hand. A diagnosis of brachial neuritis had been made by a consultant physician.

He was admitted to hospital on June 6, 1943, with a typical history of acute appendicitis of 12 hours' duration. Operation was immediately performed, and an acutely inflamed appendix was revealed. The appendix was unobstructed and not perforated, and there was but little local peritonitis. A routine appendicectomy was performed without any unusual soiling of the peritoneum or abdominal wall with the contents of the appendix, the abdomen being closed without drainage. The operation was followed by an uneven recovery until the ninth day, except for slight pain in the hand due to the brachial neuritis. On that day the patient complained of an aching pain in the lumbar region. Examination revealed tenderness of the lumbar muscles, but no spasm. Further questioning disclosed that the ache had been present in a mild form on the sixth day. A diagnosis of lumbago was made.

On the tenth day after operation there was slight stiffness of the jaw, and examination of the lumbar muscles showed a slight but definite spasm. A tentative diagnosis of tetanus was made, and this was substantiated later in the day by the development of difficulty in swallowing. The patient also complained of the sensation of being periodically kicked in the back. This was presumably due to the onset of localized tetanic spasms. 180,000 i.u. of A.T.S. was immediately given intravenously, and chloral and potassium bromide, 20 gr. of each, were administered four-hourly.

The patient's condition deteriorated for the next two days, and he complained of tightness of the chest. Marked opisthotonos, abdominal rigidity, and trismus developed, but the bromide and chloral sufficed to keep the spasms local and infrequent. On the third day however, paraldehyde, 4 dr. twice a day per rectum, was required to control the spasms. Later the paraldehyde had to be given six-hourly in doses of 6 dr. to produce the required effect. Tribromethol was not used because of the increased liability to respiratory complications, and pethidine and chlorotone were found to be less efficacious than paraldehyde.

The fifth day, when several generalized spasms were experienced, was probably the worst day. Then improvement began with disappearance of the rigidity of the abdominal wall. On the seventh day 100,000 i.u. of A.T.S. was given. As the condition improved less-sedative drugs were needed. Nutrition was maintained at a fairly adequate level throughout with glucose and milky fluids, without having to resort to a stomach tube. It was very important to feed the patient rapidly and efficiently just before the next dose of sedative was due. Then he was just conscious enough to feed, and yet the trismus was reduced and swallowing did not provoke the onset of generalized spasms.

A bacteriological diagnosis of tetanus was not made. There was a slight purulent discharge from the wound, swabs from which revealed no evidence of tetanus bacilli. Their absence was probably due to the fact that a specimen could be obtained only from the superficial part of the wound. The wound was not explored.

There was no history of any injury, and the appendicectomy wound was the only possible focus for the growth of the tetanus bacilli. The catgut used at the operation was made by a reputable firm of manufacturers. When the tetanus became manifest it was not possible to trace the batch of catgut which was used and so test it for the presence of spores. Present-day catgut is an unlikely source of tetanus spores. It seems likely that the wound was contaminated by spores from the bowel lumen. It is stated by many authorities that tetanus spores are occasionally found in the lumen of the human bowel.

I wish to thank Mr. A. H. Southam for permission to publish this case and for his helpful criticism.

A. JOLLEYS, M.B., Ch.B.,

Surgical Registrar to Out-patients, Manchester Royal Infirmary.

## Reviews

### MENTAL GROWTH OF CHILDREN

*The Mental Growth of Children from 2 to 14 Years. A Study of the Predictive Value of the Minnesota Preschool Scales.* By Florence L. Goodenough and Katharine M. Mauter. (Pp. 130. 52.50 or 15s. 6d.) Minneapolis: University of Minnesota Press; London: Oxford University Press.

This is No. 19 of the series of monographs from the Institute of Child Welfare of the University of Minnesota. In it the results of repeated tests of the intelligence of the same children over a substantial period of time are described. The tests used are the Minnesota pre-school scales, revisions of the Stanford Binet and the Arthur performance scale, and the Minnesota College ability tests. At all ages the tests proved of predictive value. It was found that there is a good deal of inconstancy in the results of tests, especially in the early years, so that single tests are apt to be misleading and the longitudinal method here advocated would seem to be much more reliable. It proved difficult to follow many children through the whole 12-year period, but others of corresponding status were brought into the series, and the authors consider that their results are statistically valid.

Details of method and of results are given, and it would appear that individual mental growth does not always proceed at a fixed and uniform rate, though in the majority of cases constancy rather than inconstancy is the rule. Irregularity is most noticeable at early ages: there may be early precocity which does not last or early slowness with subsequent acceleration. Such irregularities are not necessarily due to external causes only. The old pre-school tests have not proved to be reliable, and new tests have been and still need to be worked out. The present study has shown that trustworthy indications of special abilities and differences of mental patterns can be detected at a much earlier age than was supposed. There is a suggestion that there may be a sex difference in the age at which mental tests begin to have a predictive value for future intellectual standing. It would appear that there is an initial feminine precocity which may be reversed later on. Further work is required and will be undertaken to amplify and confirm the findings.

This is a well-documented book with a useful bibliography at the end, and it will prove interesting and valuable to all who are concerned with the mental development of the child. The authors make it clear that there are many unsolved problems in the field of mental testing and that much work still remains to be done.

### THE HUMAN FOOT

*The Foot.* By Norman C. Lake, M.D., M.S., D.Sc., F.R.C.S. Third edition. (Pp. 452; illustrated. 15s.) London: Baillière, Tindall and Cox, 1943.

Mr. Lake's book has not undergone any drastic changes during his preparation of a third edition. The most significant changes are the closer attention given to those foot conditions which are seen more frequently in wartime, such as those associated with cold, damp, or excessive strains.

True frost-bite is stated to be a much rarer condition than trench foot, but with the present tendency to rapid movement in military tactics, compared with the more static methods in the last war, the incidence of trench foot is likely to fall. On the other hand, true frost-bite has become more common as the number of high-flying airmen increase. The reference to foot strain in industry and military service is important. Long hours of standing on a concrete floor bring many industrial workers to their doctors or to hospital, where this general excessive strain on a static foot is found to be a frequent cause of disability, though aggravated in many cases by more obvious deformities such as flat-foot. The soldier who complains of pain in the foot with no obvious cause may well respond to a more gradual introduction to "foot-slogging" than is customary.

Without doubt this is an exceedingly useful book for the doctor in general practice and the orthopaedic house-surgeon, and it should help the regimental medical officer to keep the Army soundly on its feet.

## TECHNIQUE OF PASTEURIZATION

*Pasteurization.* By Harry Hill, F.R.San.I. (Pp. 152, 10s.) London: H. K. Lewis, 1943.

Much has already been written about the public health aspects of pasteurization, and convincing evidence has been brought to show the need for heat treatment of milk in this country if a great deal of unnecessary disease is to be prevented. What is required now is a small book on the technique of pasteurization for the use of plant supervisors and operators, for medical officers of health and sanitary inspectors, and for laboratory workers in the public health field. The small volume by Mr. Harry Hill entitled *Pasteurization* goes some way towards meeting this need. The author sets out to convince the reader of the necessity for pasteurization, and then goes on to consider the various processes by which pasteurization of milk may be effected. Neither of these aims is achieved with complete satisfaction. The discussion on the public health aspect is too condensed to be convincing, and the description of pasteurization technique is too general to be of much help to those who already have some knowledge of processing but would like a great deal more. It is curious that the author should have attempted this part of his task without including a single diagram, chart, or photograph in the book, and only three tables. Everything is left to the reader's imagination—the appearance, size, and lay-out of pasteurizing equipment, the internal structure of rotary pumps and of plate and tubular heaters, the design of the different types of bottle-washing machines, the relation between temperature and creaming capacity, and numerous other practical points for which simple textual description is inadequate. However, for those who want merely a general idea of the methods by which milk is pasteurized the book will be found of value.

## Notes on Books

Mr. H. C. RUTHERFORD DARLING's handbook *Surgical Nursing and After-treatment*, first published 26 years ago, has now reached an eighth edition (J. and A. Churchill; 12s. 6d.). In his preface the author acknowledges the co-operation of his colleagues at the Prince Henry Hospital, Sydney, for many hints and suggestions in revising his text and bringing it up to date. Admittedly surgical nursing is best learnt by actual experience in a well-equipped modern general hospital; but practical knowledge needs reinforcement, and the purpose of this little book is to elucidate the details and to reduce the duties of a nurse to a state of orderly sequence, so that practice and theory may be integrated. Much of the information and guidance in its 660 pages will prove helpful to surgical dressers and practitioners, as well as to the nurses for whom it was written.

Two sanitary inspectors, Mr. H. HILL and Mr. E. DODSWORTH, have collaborated in preparing a handbook for public health students entitled *Food Inspection Notes* (H. K. Lewis and Co.; 6s.). It is designed as a brief guide to present-day knowledge of the subject, stripped of all superfluous matter, and within its limitations should prove useful for revision before the candidate takes his examination. The legal aspects of the matter are not touched on.

## Preparations and Appliances

## PLASTICS IN SPLINT-MAKING

Mr. JAMES P. CAMPBELL, M.B., F.R.C.S.Ed., deputy surgeon-in-charge, Harlow Wood Orthopaedic Hospital, near Mansfield, Notts, writes:

Splint-making is a craft which is as old as the medical profession itself and is one which has a wide appeal, as it affects the work of the general practitioner and specialist alike; none more so than the orthopaedic surgeon, for whom it is an integral part of his daily work. The use of any new material in splint-making is therefore bound to arouse interest even though it is still in the experimental stage. A final statement as to its durability cannot be made until it has been put to the test of time. Plastics in one or other of their many forms may prove a valuable addition to those materials already in use in splint-making.

Any material which is light in weight, is easily moulded, and which retains its shape when fashioned is worthy of a trial in the manufacture of splints. "Perspex" (methyl methacrylate)—one of the group of plastics—is such a substance which

has the added advantages of being non-absorbent, practically non-inflammable, and (so far as we know) non-irritant to the skin. It is as transparent as glass and casts no shadow, nor is there any distortion to x rays. In addition, it is tasteless and odourless and resists both acids and alkalis.

Perspex is supplied in sheets of varying size, and the sample under trial were 3/16 in. in thickness, but other thicknesses can be obtained. It can be cut and drilled when cold, but it is important to remember that bending and moulding can only be performed when it is in the plastic state, and this requires a temperature approximating that of boiling water. If attempts are made to bend it at too low a temperature it will crack, and cracks cannot be repaired, as one might imagine, by heating to the plastic state.

**General Principles.**—Perspex can be cut in simple shape with a hack-saw, but curves are more easily cut with a fine bladed fretsaw, and a little water will be found helpful when the saw is being used. Holes can be drilled with an ordinary drill such as that used in wood-work and metal-work. The edges can be rounded off with a file and if necessary smoothed with glass-paper or emery cloth. Moulding requires preliminary heating either in boiling water for two minutes or in front of a fire until the material becomes malleable. It can then be readily moulded to the desired shape, which must be retained until it is cool, and this may be hastened by immersion in cold water. Further adjustments in shape can be made by reheating. Simple curves can be moulded by hand, but the more complex forms require a cast similar to those used in making block-leather splints. Two pieces of perspex may be cemented together with diakon cement, which is perspex in liquid form. The edges must be clean and fit closely; the cement is brushed on one half and the other quickly applied; light pressure is maintained for 12 hours in a warm temperature to allow the cement to set. The splint may be polished with special polishes—No. 1 and No. 2—to remove minor scratches and to give a finish to it.

**Method of Splint Construction.**—In making a splint from perspex the pattern in paper is first drawn on the paper-covered perspex and then cut out with a fretsaw. The edges are rounded off with a file and glass-paper. The perspex is then heated evenly throughout its length over a stove until it is soft and plastic. It is then bandaged to a cast and immersed in cold water for 1/2 to 1 minute. This process is repeated until the desired shape is obtained. Small drill-holes are then made at the appropriate levels for the straps to retain the splint in position. Before finally fixing the buckles and straps the splint is polished.

Splints made from perspex have certain advantages over metal and leather splints. They are lighter and less conspicuous; they are more hygienic in that they can be removed and washed with soap and water; they require less labour in manufacture as the finishing is more simple and padding or lining is unnecessary. The material can be used over and over again by simple heating and remoulding.

Perhaps its most useful field will be in cases of anterior poliomyelitis, as the lightness of the splint is of great importance in this condition, particularly in childhood, and perspex fulfils this need. This also applies to some types of nerve injuries such as wrist-drop of radial nerve paralysis. A further group of cases in which perspex splints may have definite advantage is where soiling is liable to occur. This applies to corrective splints for the lower limbs in infants and young children in the treatment of the deformities of rickets and where splints are required in incontinent patients.

The cost of splints made from perspex, so far as this can be estimated, may well be less than that for similar splints in metal, as the material costs almost the same and time in finishing a perspex splint is much less than that required to line and finish a metal splint.

B. Whitehall (*Johns Hopk. Hosp. Bull.*, 1943, 73, 265) records a case of severe cerebral malaria due to *Plasmodium falciparum* in a soldier aged 25. Recovery followed the use of quinine intravenously. The urine and blood-pressure findings agreed with those of acute glomerular nephritis.

## BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 29 1944

## PULMONARY EMPHYSEMA

Pulmonary emphysema and its ally chronic bronchitis are two of the most distressing conditions with which a physician can be faced. The inexorable progress of the disease induces a despair in both patient and doctor, which the weary repetition of "mist. tuss. expect." does little to relieve. Many a physician thinks himself fortunate if he can divert such a patient to his houseman or to the casualty officer. So when a physician-physiologist turns his attention to such a chronic disease as emphysema, as Prof. R. V. Christie does in his Goulstonian Lectures published in this and last week's *Journal*, we welcome the brave attempt to throw new light on an old problem.

Laennec<sup>1</sup> gave the first detailed description of pulmonary emphysema. He considered the primary condition to be a bronchial catarrh which caused partial obstruction of the smaller bronchioles: as inspiration was a more powerful act than expiration, air tended to be trapped in the alveoli, which filled out and burst. Gairdner<sup>2</sup> and others, however, contended that the primary condition was some disease causing collapse or fibrosis of parts of the lung, which was followed in turn by distension of the remaining alveoli. Freund<sup>3</sup> and Loeschke<sup>4</sup> believed that spinal deformity and fixation of the chest in a position of inflation caused emphysema, and operations to correct this deformity were devised. Degenerative changes in the lungs, both vascular and nutritional, have also been called in to explain emphysema. A common assumption is that emphysema is associated with over-distension of the lungs, and many a student has treasured in his mind a picture of the purple-faced trombone player rending his alveoli in a mighty effort. But Christie states that the emphysematous lung only appears distended when seen at necropsy, because, unlike a normal lung, it does not collapse. He shows that the residual air in emphysematous subjects is increased only slightly, and that the lungs are often no more distended than normal lungs in moderate inspiration. As Christie has pointed out previously,<sup>5</sup> no man need hesitate to join a brass band for fear of emphysema.

Sir John Floyer in 1698 noticed that the emphysematous lung lacks elasticity. Writing of broken-winded horses in his *Treatise of the Asthma*, he described the "rupture and dilatation of the bladders of the lungs" so that "the air blown into any lobe will not be expelled thence by the natural tone of the muscles of the bladders." As Thomas Watson<sup>6</sup> commented nearly 200 years later: "Really this

is a capital piece of pathology for the seventeenth century." Loss of the normal pulmonary elasticity forms the basis of Christie's theory of the mechanism of emphysema; he considers it the most important abnormality in the emphysematous lung. He found the intrapleural pressure in several emphysematous subjects to be raised and often atmospheric, even at the end of inspiration. The elastic tension of the lung produces the normal negative intrapleural pressure, the abolition of which Christie takes as an indication of a loss of pulmonary elasticity. The weakened inelastic alveoli tend to dilate. The resulting enlargement is most noticeable close to the surface of the lung, where the pull of the chest wall and diaphragm is greatest: emphysematous bullae are commonly situated in this area. Expiration, as is well known, is largely a passive movement produced by the elastic recoil of the lung, and if this is abolished the chest would expand, owing to the overaction of the muscles of inspiration, thus producing the emphysematous deformity. Christie has shown that such expansion actually occurs when the pulmonary tension is abolished by an artificial pneumothorax.

The oxygen saturation of the arterial blood in emphysema is diminished in proportion to the severity of the disease and can be increased by giving oxygen (Meakins and Davies<sup>7</sup>). The ventilation in the lungs is therefore clearly deficient. The blood  $\text{CO}_2$ , on the other hand, is much increased and so is the alveolar  $\text{CO}_2$ ; this suggests that a free gaseous interchange can take place through the alveolar walls. What is the explanation of this diminution of the oxygen and increase of the carbon dioxide in the blood and alveolar air in emphysema? Defective respiratory mechanism does not cause it, for the volume of the tidal air is not decreased. Insufficiency of functioning lung causes decreased  $\text{CO}_2$  elimination as well as decreased  $\text{O}_2$  absorption: so this cannot be blamed. Nor can one blame poor ventilation of the alveoli from distortion of the terminal bronchioles: gaseous exchange is so quick that such a defect could not impair the exchange of gases. Christie's explanation is that the inspired air tends to be drawn into the dilated and avascular alveoli and bullae at the expense of the more normal alveoli, which come to depend almost entirely on diffusion for their ventilation. Such an unequal ventilation in emphysema would account for both the insufficient oxygenation of the blood and the failure to eliminate  $\text{CO}_2$  from the lungs. The dyspnoea is clearly due to the high blood  $\text{CO}_2$ , which even a much-increased bicarbonate reserve fails to prevent.

As to the actual cause of emphysema, Christie contends that the repeated strains on the alveolar walls during coughing or the obstructed breathing of asthma account for the loss of pulmonary elasticity. He draws attention to the almost invariable association of chronic bronchitis or asthma with emphysema, and to the fact that several workers have recorded increased alveolar pressures in these conditions. This theory, he admits, does not explain the occasional instances of emphysema in which there is no evidence of bronchial disease, but it helps to clarify much that was hitherto obscure. Nevertheless, the older theory of chronic obstruction will probably continue to have its supporters. As long ago as

<sup>1</sup> *Traité de l'Auscultation Médiate*, 1819.<sup>2</sup> *Mithy. J. med. Sci.*, 1849, 9, 242.<sup>3</sup> *Dtsch. med. Wschr.*, 1913, 39, 603.<sup>4</sup> *Handb. spec. path. Anat. Histol.*, Berlin, 1928.<sup>5</sup> *Edinb. med. J.*, 1939, 46, 363.<sup>6</sup> *Principles and Practice of Physic*, 4th ed., London, 1857.<sup>7</sup> *Respiratory Function in Disease*, Edinburgh, 1925.

1885 Brown-Séquard<sup>8</sup> noticed that when stimulation of the mid-brain produced bronchial spasm in a dog the alveoli dilated. This observation has since been confirmed, and it has been suggested that bronchial spasm may be present in all cases of emphysema, even when it is not clinically demonstrable. Kountz and Alexander<sup>9</sup> have shown that administration of adrenaline improves the vital capacity of patients with uncomplicated emphysema, as well as of those with bronchitis and asthma, thus supporting this suggestion. Chronic obstruction would also explain the intrapleural pressure changes. Christie, as Cabot,<sup>10</sup> Davidson,<sup>11</sup> and others before him, has found emphysema at the necropsy of patients who showed none of the classical signs of the disease during life. The barrel chest—the commonest diagnostic criterion—may also often be a postural deformity unassociated with emphysema. Of more value is the history of increasing dyspnoea on exertion in a chronic bronchitic or asthmatic.

A quick glance at these investigations might lead the practising doctor to think that they are largely of academic importance. But they point to three valuable methods of treatment which, though not new, are often neglected. Christie emphasizes once more the value of ephedrine—often very effective in relieving the dyspnoea of emphysema even when bronchial spasm is not evident. Respiratory exercises designed to improve diaphragmatic breathing and mobilize the lower chest are also most useful, especially in cases of marked thoracic deformity. Finally, Christie agrees with Kountz and Alexander in recommending the use of an abdominal belt which helps to raise the diaphragm. Application of these practical measures should ensure at least that the emphysematous patient leaves hospital with less dyspnoea, a more mobile chest, and a better-corseted abdomen.

### A NEW BRITISH JOURNAL

This week sees the publication of the first number of the *British Journal of Industrial Medicine*, whose advent was allded in these columns in an annotation a short while

<sup>12</sup> It owes its origin in the first place to that active group comprising the Association of Industrial Medical Officers, which was formed in 1935 to bring together medical men employed whole-time in various branches of industry so that they could pool their experiences and forward their common aims. As the editorial pen records, the new association got much valuable guidance from Sir Wilson Jameson, who was then dean of the London School of Hygiene and Tropical Medicine. The association grew rapidly and now has more than 300 members, to whom the new journal will mostly look for its inspiration and original work. The *B.J.I.M.*, which is being published from Tavistock Square by the British Medical Association, will, it is hoped, play more than a passive part in furthering knowledge in the field of industrial medicine. Its very existence should stimulate those whose professional work brings them into contact with industry to look at old problems with new eyes, to find fuller answers to

old questions, and to start asking new questions, the answers to which will come out in work that can with truth be described as original.

Although, like the other three special quarterly journals published by the B.M.A., the new quarterly is first and foremost scientific in nature, the list of contents of No. 1 shows that the Editors are not afraid to provide that good mixed diet held to be the height of nutritional excellence. This pleasant foretaste of editorial policy convinces us that the *B.J.I.M.* will appeal to a much wider audience than the relatively small number of men now engaged whole-time in industrial medical practice and research. As Lord Moran says in his most apt foreword, written in a style which has his hall-mark: "The firms that in bulk bear the main burden of the day are generally too small to have a whole-time works doctor. They will look for help to the general practitioner, and there is nothing in the nature of industrial medicine which is beyond the competence of a sound practitioner." Lord Moran agrees, of course, that special training is required for factory work and that an industrial doctor must be familiar with working conditions and industrial hazards: "But first and last he must be a good doctor. If he is, all the rest will be given unto him."

No. 1 of the *B.J.I.M.* can certainly give him a good deal. It starts off with an article by Prof. Major Greenwood entitled "The Evolution of an Industrial Society." The author in one sentence shows how much of what we may call "industrial medicine" is simply part and parcel of medicine as a whole: "Had our ancestors wholly neglected the evils of life in factories, left young persons without the protection of laws and inspectors, disregarded extra-domestic evils, *but rehoused the people* [our italics], I think the rate of mortality would have begun to fall a century sooner." In one sense, then, industrial medicine is domestic medicine writ large, as we are reminded by the inclusion in this issue of the *B.J.I.M.* of articles on heating and ventilation by Dr. T. Bedford, on nutrition and the industrial worker by E. H. Capel, on some foot faults related to form and function by Mr. W. Sayle Creer. Heating and ventilation and nutrition—housing and food—are after all the first problems of domestic medicine and of social medicine. Some aspects of these problems may well first be studied in the factory and the workshop, and the lessons learnt be applied afterwards to the home—the medical province, as we like to believe it, of the family doctor.

There are of course the special problems of industry, more especially those of toxicology, as the article by Alice Stewart and L. J. Witts on chronic carbon tetrachloride intoxication reminds us. But perhaps the largest scope for inquiry by the medical man who has a whole-time or part-time special interest in industrial medicine is provided by the study of the individual undergoing the various stresses and strains of any given environment. How, for example, will the woman whose overactive thyroid has been removed stand up to her job in the textile factory? The factory and the workshop also give the doctor and the welfare worker an opportunity to find out how people live and to give them that instruction in personal and communal hygiene which this war has so clearly shown to

<sup>8</sup> *C. r. Soc. Biol.*, Paris, 1885, 37, 354.

be necessary. What can be done in the way of investigating health and disease in a large group of employed people is a lesson that we in this country have learnt from the Post Office Medical Branch, under its recent chief medical officer, Sir Henry Bashford, who saw this first number of the *B.J.M.* to press and who contributes an article to it on some aspects of sick absence in industry. His appointment as Medical Adviser to the Treasury made it impossible for him to continue in his post as Chief Editor, in which he was succeeded by Dr. Donald Hunter before the first number came to light. We would, however, like here to record that he has been the moving spirit behind this new venture. The last article in No. 1 is contributed by a distinguished representative of industrial medicine in the U.S.A., Dr. Orlen J. Johnson, who writes on medical service in industry in the United States. This shows that the new journal, though British, is not going to close its columns to articles from men working in other countries on the common problems of industrial medicine.

### AN INCREASE IN DIARRHOEAL DISEASES

Those who study the epidemiological tables of the *Journal* find almost every week something to stimulate their interest. Thus in the issue of Jan. 15 they noted with some excitement that notifications of diphtheria for the English great towns had dropped below 500 in the last week of 1943, which suggests that prophylactic immunization is already having an appreciable effect. On the other side of the picture, as the analysis on page 125 last week showed, is a recent increased incidence of scarlet fever, and—much more serious—a sharp rise in the war years of notifications of dysentery and of deaths from enteritis in children under 2 years of age. Indeed in 1943 more than three times as many children died of enteritis than of diphtheria in the large towns of England and Wales. It may be that a proportion of cases certified as dying of enteritis should be attributed to other causes, but this error is not likely to vary much from year to year, and does not explain the steady trend upwards of deaths from 1,812 in 1940 to 2,569 last year. An even more striking increase in the notifications of dysentery (from 2,843 in 1940 to 7,772 in 1943) can only partially be explained by a greater awareness and better diagnosis of this, now endemic, infection. These increases in diarrhoeal diseases at a time when the infant mortality rate is improving must give us pause.

Dysentery in this country is a mild disease of high infectivity, and if, as is often stated, its incidence reflects the standard of personal and public hygiene in the community we must suppose that there has been some falling-off in these standards since the war began. A variety of reasons suggest themselves: a great increase in communal feeding, the multiplication of day and residential nurseries, labour shortage interfering with the cleanly handling of food and milk (a number of milk-borne outbreaks of dysentery have lately been reported), and probably mass movements of troops and civilians. But we need also to consider if there has been some lowering in the host-resistance due to improper feeding or physical or mental fatigue. Dysentery is mainly spread by the contamination of food with soiled

fingers, but too often the mildness of the disease means that the culprit cannot easily be detected. Add to these missed cases the contact and convalescent carriers, now shown by selective culture media to be much more common than was formerly believed, and it is understandable how difficult a disease dysentery is to eradicate. Only a high standard of personal hygiene in the community, and particularly among food-handlers, will control its spread, and propaganda to this end is urgently needed. The Food and Drugs Act (1938) gives the M.O.H. new and wide powers in dealing with premises and personnel where food is sold.

Infantile diarrhoea, if less prevalent than dysentery, is a much more fatal infection, and ranks next to neonatal deaths and pneumonia as a cause of infant mortality. Its aetiology is complex, but its ravages could be largely prevented if a majority of mothers could or would breast-feed their babies for 6 to 9 months. Here again enlightened propaganda<sup>1</sup> and much concerted effort by family doctor, ante-natal and child welfare clinic, maternity department, and the mothers themselves would encompass a great saving of lives. While some 80% of mothers delivered in institutions and 95% of those confined at home breast-feed their babies for the first few weeks of life, the proportion has dropped to 50% or less at 3 months and 30 to 40% at 6 months. With a great increase in institutional midwifery much depends on the nursing staff of the maternity unit in establishing satisfactory breast-feeding, and no unit is doing its job properly that cannot discharge about 90% of wholly breast-fed babies. Too often, however, much painstaking effort in the maternity home is undone when the mother, returning after 10 days to the worries of a household, either cannot or will not continue with breast-feeding. In this she may be aided and abetted by her family doctor, who is sometimes too ready to recommend artificial feeding when a little encouragement and advice would ensure continuance of Nature's way. Nor are welfare clinics entirely blameless, especially when their posters proclaim the virtues of this and that brand of dried milk. It must not be forgotten, however, that infantile diarrhoea affects principally poor-class urban children, so that factors other than artificial feeding operate. For example, are the salvage campaign and the collection of pig-food, which helps to breed flies, a contributory cause of the greater prevalence in the war years? Is there a falling-off in the cleanliness of milk due to less careful handling and poorer distribution? Are children with minor digestive upsets too readily certified and too easily admitted to hospital, and is hospital cross-infection more prevalent because of shortage of nurses? Again, outbreaks of neonatal diarrhoea, with its appalling mortality, have been more common in recent years, and this infection, too, occurs mostly and in its severest form in bottle-fed babies. The attack on the whole problem of infantile enteritis seems to be along the lines of intelligent advice and propaganda for the mother about breast-feeding, more effort in maternity units to attain a 90% discharge of wholly breast-fed babies, and, most important, more help when the mother again takes up the onerous duties of housewife.

<sup>1</sup> See Rep. on Publ. Hlth. and Med. Subjects, No. 91: *The Breast-feeding of Infants*, 1943. (4d.)

### INFANT MORTALITY IN BELFAST

The most notable feature of the mortality experience of the present century is the decrease in infant mortality, which has fallen by two-thirds in England and Wales. Striking as this reduction is, much lower rates have been attained by some countries. Infant mortality in the large towns of Great Britain has lagged behind the country as a whole. That conditions of life in big cities need not be associated with a severe mortality risk to infants has been demonstrated in America, where very low rates have been recorded—e.g., in 1942 the infant mortality of New York was only 29 per 1,000. It is obvious that there is ample room for improvement in the British rates, and it seems to be within the bounds of possibility that infant mortality in large cities can be reduced to at least 25 per 1,000. The city of Belfast is unfortunate in having one of the largest infant death rates in the United Kingdom. The deaths of infants in this city have fluctuated from 1 in 12 to as high as 1 in 8 in recent years, and judging by existing standards about three-quarters of these deaths were preventable. To put it another way: over 500 babies die yearly who apparently could be saved. An investigation into the various aspects of this mortality in Belfast has been made by Deeny and Murdock.<sup>1</sup> The data comprised the deaths between June, 1941, and June, 1942, and a random sample of one-fifth of the children born in the first six months of this period who survived the first year of life. Premature birth and injury at birth accounted for one-quarter of the deaths; another quarter was due to respiratory diseases, and one-fifth to diarrhoea and enteritis. The environmental indices—income and housing conditions—were related to infant mortality: the former had the larger association, but rather surprisingly no significant relation could be demonstrated between dirty homes and mortality. The deaths from diarrhoea and enteritis and respiratory infections formed a larger proportion of the total infant deaths in the lowest income group than in the highest. An attempt was made to determine the adequacy of the medical attention by examining the individual cases. Medical aid was sought as promptly in the illness that ended fatally as in non-fatal sickness. The authors found that parents were quick to call in the doctor, and the poor secured medical attention as early as those who were better off. Nutrition is of first importance in the rearing of healthy children, and the relation of feeding to infant mortality is discussed by the authors elsewhere in this *Journal*. The proportion of breast-fed babies was lower among the dead than among those who lived. The proportion breast-fed was practically constant in both groups of infants for the subgroups of income per head, number of persons per room, domestic hygiene, and for order of birth and cause of death. These factors had no significant influence in determining the proportion of breast-fed babies, and no relation was established between breast-feeding and mortality. The authors conclude that an increase in the proportion of breast-fed infants would not lower the infant mortality, and that the smaller proportion found among the dead was an effect rather than the cause of unsuccessful reproduction.

### SURGICAL SCIENCE MOVES FORWARD

The Scientific Report of the Royal College of Surgeons of England for the past academic year makes cheerful reading. There is a record of painstaking care of the surviving material from the Museum scattered widely over the Home Counties. Shortage of staff and difficulties of transport can be understood by most, but the attention and skill needed to conserve material from the depredations of mice,

moulds, and men can only be appreciated fully by those responsible for the care of museums. It is encouraging to read of the plans made for collection of material in special fields by College representatives chosen for their interest in them. Donors have been numerous and their gifts many and valuable. The odontological collection of the Royal Society of Medicine has been given to the College as a contribution towards the future reconstruction of the Museum.

The College has decided on its future policy concerning the Museum. An opportunity is now presented to provide not only a unique collection of anatomical and pathological material but an educational instrument of untold value. Medical museums are essentially educational. The day has long passed when they were the repositories of the surgical triumphs of bygone surgeons and bleached specimens hallowed by a famous name. The historical value of the latter far outweighed their pathological interest. It is to be hoped that in the new Museum a place will be found for Hunter's specimens, a place where honour can be done to Paget and Lister and where specimens illustrating classical work will be on view. The greater part of the Pathological Collection it is hoped will grow into a national type-collection of pathology adequately documented with clinical histories and illuminated with histological detail—these for the specialist as his reference library. For the student who wishes to see pathological processes let us hope there will be a place. The anatomical series can never be reconstituted as Hunter formed it—a collection to illustrate the relation of form to function—but perhaps it will be possible to suggest somewhere the great idea which Hunter had and which was so fruitful both before and after Darwin. In this collection, too, the collections for the specialist will be necessary, and it is to be hoped that examples of superb prosectorial skill will be available for the student of human structure.

The Research Laboratories are obviously in battle dress. Experiments on the production of casein digests suitable for intravenous medication, the prevention of liver damage during antisyphilitic treatment, the treatment of infective hepatitis, and new surgical suture material are all of topical as well as of scientific interest. As reports on these various problems will soon be published they do not call for discussion here. More significant than the problems has been the way in which these laboratories and their staff have become responsible for a large-scale clinical experiment. It must be rare for a research laboratory to have available sixty hospital beds where new methods of treatment can be worked out (under proper supervision) and where there is continuous interchange of ideas between the hospital ward and the laboratory. A significant paragraph in the report states: "This year's work has made it abundantly clear that in future there should be available to those working in the laboratories easy access to a hospital ward which is dedicated solely to the study of disease. The constant stimulus which comes from team work is immeasurably facilitated by direct contact with and responsibility for the treatment of the sick." Perhaps in the near future some such research hospital might be established on or near the College site. With the existing Research Laboratories, and the imminent developments in the Department of Pathology close by, a research centre of unlimited usefulness would soon come to maturity.

We much regret to announce that Prof. W. W. C. Topley, M.D., F.R.S., late Director of the Division of Bacteriology and Immunology, London School of Hygiene and Tropical Medicine, died suddenly on Jan. 21, after attending a meeting of the Agricultural Research Council, of which he had been Secretary since 1941.

## Reports of Societies

### ORGANIZATION OF LUPUS TREATMENT

A joint meeting of the Sections of Dermatology and of Epidemiology and State Medicine of the Royal Society of Medicine was held on Dec. 16 to discuss the organization of the treatment of lupus vulgaris. Dr. A. C. ROXBURGH presided. The subject was introduced by Dr. F. S. AIRY, who said that there was no true conception of the incidence of lupus in this country, its distribution, the facilities available for its treatment, their adequacy, the extent to which those afflicted availed themselves of the opportunities for treatment, and the success of the measures adopted. He suggested an incidence of one case per 1,000 of population, which would mean 45,000 lupus sufferers, and would justify the establishment of local treatment centres. Just as public health authorities had tackled diphtheria, so propaganda should be used to persuade lupus patients to seek treatment at an early stage. Lupus was a sociological as well as a medical problem.

Sir HENRY GAUVAIN (in a paper read in his absence) said that there should be recognized accessible centres where cases of suspected lupus could be sent for diagnosis. Severe cases of lupus in children should be treated at a resident hospital school, and adults seriously affected, in colonies. Correspondence in the *British Medical Journal* had evoked enthusiastic testimony to the Finsen-Lomholt lamp. Its drawback was its expense. He believed that, Denmark being now in enemy hands, it would be legal to undertake the manufacture of the lamp in this country. But it was deplorable that Finsen treatment should have become a fetish.

Dr. A. BURROWS praised light treatment for its efficacy. Localized patches of lupus were ideally treated at Finsen light centres; more extensive cases could be successfully treated by light, but the applications might have to be protracted over a long period. It used to be said that lupus patients did not suffer from other forms of tuberculosis, but that idea had been exploded. In many cases the patients could carry on their ordinary lives while under treatment, but segregation was sometimes desirable. Segregation had the advantage of ensuring hygienic surroundings and aseptic dressings; its drawback was the psychological effect. The proper method of organization would be *ad hoc* centres with some residential accommodation for special cases over short periods. He thought that about ten centres in England would be sufficient.

#### Incidence of Lupus Vulgaris

Dr. F. R. G. HEAF said that lupus vulgaris was a comparatively rare condition. In the five years 1931-5, out of a total of 3,624 non-pulmonary tuberculosis cases treated at L.C.C. centres, 59 were of lupus of the skin. In 1938 in Lancashire 2,032 cases of all forms of tuberculosis were notified, of which 805 were non-pulmonary, and the skin cases of lupus numbered 26. On the Lancashire registers in 1942 the number of active cases was 191, and of quiescent cases 85. In Manchester in 1940 there were 15 new notifications and in 1941 17. As treatment was costly and called for a specially trained staff, it should be located in centres which served at least a population of 5,000,000. The establishment of such centres called for regionalization and for co-operation between local authorities. He estimated that there were annually about 10 new cases of lupus per 1,000,000 population, and that five beds per 1,000,000 were required, with out-patient facilities to treat approximately 50 cases per 1,000,000. If there was much disfigurement, permanent residence at an industrial settlement like Papworth would have to be considered when the activity of the lesion had been overcome.

Dr. HENRY MACCORMAC said that he was under the impression that tuberculosis of the skin was a notifiable disease, as were other forms of tuberculosis, and therefore there should be official records of the number of cases. He believed it was an extremely rare disease, though that was no reason for neglecting it. Any attempt to regiment people into institutions would create great difficulty, but it might be possible to establish a system of occupational centres like that in Denmark.

Lupus had a geographical distribution. It was common in Scandinavian countries and, he believed, unknown in Australia.

Dr. W. J. O'DONOVAN said that if lupus vulgaris was a problem of any size and had been neglected it would declare itself in the reports of the medical boards. In the whole of one Command, covering a quarter of the country, in which all difficult contagious conditions were referred to him, he had seen since the beginning of the war only 4 cases of lupus vulgaris, and those were slight. Up to the outbreak of war this was a diminishing problem, thanks to the greater care of public health, food inspection, and smoke abatement. When he began to assist Dr. Sequeira at the London Hospital there was a multitude of horrific cases, but these diminished as the years went on, while the number of early cases sent by school medical officers increased. In a paper in 1925 Sequeira said that the Minister of Health had conferred upon local authorities ample powers to set up clinics, and he believed these were sufficiently used in the areas in and around London. The key to the lupus problem was accurate initial diagnosis. It took him five years, during which he saw lupus daily in numbers of cases, before he was positive as to the state of the skin of the patients who came under treatment. Lupus was a manageable problem. He considered that the treatment at the centres could be applied, under a skilled and experienced sister, by nurses of the category familiar in the Army as V.A.D.s. At St. Louis he noticed that many of the nurses and hospital attendants had themselves suffered from lupus, and such people, if educated and courteous, should be the very best to persuade other patients to submit to the necessary treatment.

#### No Large Public Health Problem

Dr. A. M. H. GRAY said that lupus was not a large public health problem, and therefore had not been dealt with to any considerable extent from that point of view. At the same time, dermatologists would feel that it was only right for some active steps to be taken. The problem with adults was more difficult than with children, for some of them were unable to obtain work. Some arrangements for occupational therapy were desirable. Dr. Heaf had suggested that the treatment should be centred on general hospitals with teaching schools, but in London this would mean that the number of cases at each hospital would hardly be adequate from the teaching point of view. He would prefer to see cases of lupus transferred to one or two centres where treatment could be organized on a fairly large scale. Dr. J. A. H. BRINCKER pointed out that according to Lomholt the incidence of lupus in Denmark was about 1 in 1,000 of population. An investigation in London following upon Lomholt's visit ten years ago revealed very few cases. Dr. J. T. INGRAM said that in Leeds during the last fifteen years, from an area having a population of about 2,000,000, there had been 559 cases of lupus attending the out-patient department. Of this number 138 for one reason or other had no treatment. Of the 421 cases treated 324 were apparently cured, and in 175 of these the cure had persisted for from five to ten years. About 27 cases out of the total had been marked down as incurable, but any case of lupus returning to adverse psychological, nutritional, or environmental conditions was liable to relapse. Colonization was necessary for only a very small proportion of cases.

Dr. R. T. BRAIN said that many physiotherapists appeared to be frightened of ultra-violet light. He had often referred a patient with lupus to a local light centre, and had been told that he could have two or three treatments for a week, and then must wait for two or three months. He could not understand that attitude. It was important, of course, that the patient should not have latent phthisis, and it was the custom to refer patients to a clinician for examination of the chest. The kidneys also should not be forgotten, because a damaged kidney would be disturbed by the intensity of the radiation. But these conditions excluded, a patient could be given a very high concentration over a long period. Sir WELDON DALRYMPLE-CHAMPEL said that he would have liked to hear a little more about the competence of the general practitioner to make a provisional diagnosis of the disease. A certain amount of extra instruction in this disease should be given to medical students—enough at all events to enable them to suspect a case of early lupus and refer it to an expert for diagnosis.

## Correspondence

### Research in Ophthalmology

SIR,—I have read with interest the editorial entitled "Research in Ophthalmology" in your issue of Oct. 2 (p. 426), and while this undoubtedly merited a critical reply from some senior member of the profession, so far none has been forthcoming. One must assume that the reasons advanced for the undoubted paucity of basic ophthalmic research during the past decade in this country, which you so rightly deprecate, have the tacit approval of ophthalmologists. None has seen fit to join issue with you when you attribute a large measure of the fault to those junior ophthalmologists who "slip with such ease into the routine work of well-paid refraction clinics and thus side-step junior hospital appointments with their facilities for research."

This is, however, a most biased picture of the actual situation. In the first place it must be insisted that the causes which have operated to bring about the present unsatisfactory position reside at a much higher level in the ophthalmological hierarchy than the humble, overworked, and certainly underpaid ophthalmic clinical assistant and refractionist. The eye-hospital junior surgical appointments, with or without the facilities for research which you mention, are far too few to go round, so that a large number of practitioners genuinely interested in the academic side of the specialty are grounded at their particular level with little hope of advancement and with hardly any encouragement from above. For the most part they are excluded from the general work of the hospital and confined almost rigidly to the routine of the overcrowded out-patient departments. Their lot is one of discouragement and stultification, and until this pernicious system in eye hospitals receives its final quietus (and no movement to make an end of it is yet discernible from those responsible) it seems a pity to saddle this almost inarticulate stratum of the ophthalmic world with any major share of liability for the poor output of ophthalmic research.

However, the essential reason is the one you mention—"that the time is past when advances in knowledge can be attained by relatively simple methods by a single investigator," and particularly is this true in eye work. Surgical ophthalmology has already reached a very high stage of development, and medical ophthalmology can only advance in step with advances in general medicine as they occur. In fact, therefore, it is to medical ophthalmology that we must in the future devote the major part of our effort in ophthalmic research; but so long as ophthalmology is regarded as primarily a surgical specialty, and its academic associations continue to be inspired by this conception, the dearth of research is likely to continue.

For the past few years a section of the ophthalmic profession with these matters in mind have been endeavouring to establish a Faculty or College of Ophthalmology, and it is likely that in the near future their efforts will meet with success. Such a development is likely to result in a greater general level of interest and co-operation in ophthalmic research throughout the country than the isolated local establishment of professorial chairs attached to various universities and ophthalmic institutions, which, though laudable developments in themselves, are too restricted in nature to exert any widespread or rapid influence on ophthalmic education and research generally.

It is currently accepted throughout the ophthalmic profession that a regulated portal of entry into the profession which is nationally available and which is based upon high standards of both clinical apprenticeship and academic knowledge is long overdue. None of the present diplomas in ophthalmology satisfactorily equates the criteria mentioned, nor do the projected alterations in the F.R.C.S.Eng. (so far as one knows their details) seem likely to meet the requirements of the majority of ophthalmologists in practice.

It is the absence of such a central co-ordinating and stimulating institution in ophthalmology which is the most

important single factor in the very marked meagreness of ophthalmic research in this country.—I am, etc.,

London, W.1.

LIONEL M. GREEN,  
President, Association of British  
Ophthalmologists.

### Consultant and Specialist Services

SIR,—The letter of the Presidents of the three Colleges fills me with some uneasiness at the methods employed. They refer to an existing committee of the Colleges, which consists, among others, of eleven representatives from the non-teaching hospitals. As a consultant and member of the staff of a non-teaching hospital I should be very interested to know how these representatives are nominated and elected; as a Fellow of the Royal College of Surgeons and a member of the Royal College of Obstetricians and Gynaecologists I cannot recollect ever having been given an opportunity to nominate or elect such representatives.

The next point on which I should like more information is the steps taken by the Colleges "to ascertain what consultants and specialists are available at the present time." What are the steps that are being taken?

But perhaps the most disquieting statement is that "the result of this survey will not be published; it is for the personal guidance of the Minister." These appear to be unusual methods in a democratic country. How does a consultant know whether or not he has been put on this list or left out if it is all so secret? I sincerely hope that information may be published that will allay these misgivings.—I am, etc.,

Hove.

H. J. McCURRICH.

### Future of the Mental Health Services

SIR,—Last year, when it appeared a matter of urgency to present the Minister of Health with some considered ideas on this subject, the Royal Medico-Psychological Association, like certain other bodies, prepared its tentative recommendations. Now, with rather more breathing space, the association has set up a new planning committee, under the chairmanship of Brig. J. R. Rees, designed to represent every branch of the specialty. It is hoped that in each division of the association a local committee will meet to discuss and represent the views not only of the members of the R.M.P.A. but also of any, or all, psychiatrists in that area. The committee thus hopes to receive a number of considered plans, but, in addition, it will welcome all relevant suggestions put forward by any group or by individual physicians. The mental health of the nation is of paramount importance, and accordingly the future organization of the mental health services merits most careful thought.

All such communications can be sent to me as below, anonymity being preserved if desired.—I am, etc.,

11, Chandos Street,  
London, W.1.

W. GORDON MASEFIELD,  
Hon. Secretary, Medical Planning Committee,  
Royal Medico-Psychological Association.

### Returned Prisoners of War

SIR,—May a psychologist congratulate Major P. H. Newman (Jan. 1, p. 8) on his statement of the difficulties of the returned prisoner of war. It might be criticized as only naked-eye pathology, but no claim is made to anything deeper; psychiatrists welcome his first-hand experience and observations, and what might be a defect becomes an advantage when the object is to appeal to the ordinary doctor to recognize and understand the condition of these men. Yet my experience in the treatment of ex-Service men after the last war leads me to amplify or qualify some of his statements. Thus the choice of escaping and sabotage as one way of leading a constructive life is too simple a view, even when qualified by the remark that the choice depends upon temperament. I believe it is technically the duty of every prisoner of war to try to escape, but when I listened to a radio account of a man who succeeded after four attempts, though the victim of savage punishment and the witness of the shooting of a fellow venturer, I recognize his state as probably identical with that of other men whose repeated efforts to escape depended upon a pathological compulsion that persisted in other form—a tendency to fugues, for example—after return to civil life.

A more useful broadcast would be extracts from Major Newman's account of the effects of the deprivations and frustrations of the men behind the barbed wire.

Major Newman, perhaps because of the surgical outlook that persistently regards nerves as corporal structures, avoids that thought-stifling witch word *neurosis*, though he falls down once on *neuritic*. This makes more surprising his view that individual psychological treatment for any returned prisoner of war is "debatable" because "it may carry with it a public acknowledgment of mental abnormality, which must at all costs be avoided." This reminds us of, "He's not mental, doctor; it's his nerves," and is a poor reason for depriving the men of treatment that is now available for civilians in psychiatric clinics all over the country. I can assure Major Newman that the difficulty he pictures is quite familiar, and the solution is to remove the stigma from "mental." To-day I saw a letter from an ex-N.C.O. with 3½ years' service in the R.A.F., invalidated out for what he says was "anxiety psychoneurosis," who asks for treatment, and writes, "I find life very hard at the moment as I am not doing any regular work," then describes how he worked for six months, but "became worse and came back home where I have been ever since, doing odd jobs of work for my parents." Would Major Newman deny this man individual treatment (supposing it is desirable) lest it might involve public acknowledgment of mental abnormality?

I hope he will carry on the good work and place himself on the side of the psychiatrists, some of whom were struggling on behalf of their soldier patients a quarter of a century ago—often in the face of somewhat sadistic moral judgments used as diagnostic criteria—for the same understanding and tolerance that he now seeks for the troubles of the men whose cause he champions.—I am, etc.,

London. W. I.

MILLAIS CULPIN.

### The Prisoner-of-War Mentality

SIR.—As a slight relief from the depression which Dr. Richardson Billings's letter (Jan. 15, p. 90) might have caused in the minds of relatives of prisoners of war in the Far East, I should like to mention that in the beginning of this month I received from my elder son, Major G. F. Harrison, R.A.M.C., who is a prisoner of war in Camp A, Hong Kong, three postcards, dated respectively March 14, July 11, and Sept. 12, in one of which he said: "We have a very good library, and, when there is time, I am sampling the contents with pleasure." In another, after mentioning that he had read the whole of Shakespeare's works, he said he was glad to have the opportunity "to read stuff I never seemed to have time for before." Incidentally, in one card he said that he had seen in a local paper dated June 18, 1943, mention of an article of mine that had been published in the *Spectator* for the week previously. This quotation must have been derived from a German broadcast in which the article was mentioned during the week following June 11.—I am, etc.,

London. S.W.1.

L. W. HARRISON.

### Shock Therapy

SIR.—Dr. Winnicott's letter (Dec. 25, p. 829) should be taken not so much as a challenge to innovations in psychiatry but as a warning for us all to pause awhile and think seriously about the general direction in which medical progress is taking us to-day. We live in a world of "action and reaction." If a certain course of action is pursued long enough that it is not favourable to or in keeping with the internal economy of the "organization" or "organism," some catastrophe will be precipitated. In broad principle this is an inescapable truth and is universally applicable: if we think in terms of nations the catastrophe will be revolution or war; if in terms of industry, a strike; if in terms of the physical body, physical illness; if in terms of the mind, neurosis or psychosis.

We know very little more about the actual acquisition of disease than our forefathers did, or the real reason why a person falls ill. True we know a great deal about bacteria, viruses, etc., and enormous advances have been made in controlling the growth of these organisms; but what has modern medicine given us to enable a man to say: "I am proof against

disease" (unless of course he has been artificially immunized)? Is it really to the advantage of the human race that all our energies should be devoted to the "repair shop"? The more efficient we make the palliative side of medicine, the less urgent will be the need to look to ourselves, our habits of life, etc., as possible "courses of action" which are unfavourable to, or not in keeping with, the internal economy of the human organism.

Other contributors have ably pointed out that psycho-analysis does make an endeavour to understand why a person is ill as well as how. It is more than a mere therapy; it is a science based on the understanding of the interplay of conscious and unconscious forces. In judging the therapeutic properties of any "cure" we fall into error if we consider only the effect it has upon the symptoms of the illness and ignore the known pathology of the condition. In 1917 Freud outlined the psychopathology of depression (*Mourning and Melancholia*), and since then analysis has shown clearly that it can be regarded as a normal phase through which the child passes (though, of course, seldom observed as such). It would seem that the advocates of shock therapy will have to do one of two things: either think of the therapy in terms of what happens in the transference relationship with their patients by the introduction of fits, or else work out a new pathology in a physiological setting and demonstrate how the fit alters this structure.

It may not be without significance that nearly all the reports on shock therapy given by the administrators minimize the anxiety experienced by the patient and stress the harmlessness of the procedure. As a psychiatrist I have now had the opportunity of seeing quite a number of patients who have received this treatment at different centres. When telling me about the treatment they have nearly all stressed the terrifying nature of the procedure. This marked discrepancy of findings is, I think, most enlightening. It can be taken as a clue to the nature of the unconscious transference relationship initiated by the fit—one in which the aggressive component predominates, with its affect of hate and the reaction formation of terror; they are thus canalized and bound into this relationship and the patient is thereby freed. If this be true, then it would follow that the patient would repress the memory of his actual experiences and substitute some pleasing account for the benefit of the physician, and only later, to a sympathetic but otherwise disinterested person, can they tell the real facts. I would even go so far as to say that all reports given by these patients to any member of the staff of the hospital might be so biased as to be quite worthless, but would be very interesting as to what a patient can say and do under a certain set of circumstances which are not in keeping with his internal economy. This mechanism was clearly seen in a case of paranoia with delusions of persecution I was treating with insulin coma. He quite rapidly lost his delusions and substituted an ingratiating attitude. During the three months after conclusion of this treatment there was a gradual diminution of this "pleasing" attitude, and then a fairly sudden swing to the negative phase in which I was the predominating character in his delusional system of persecution.—I am, etc.,

Bishops Stortford.

D. N. HARDCASTLE.

SIR.—With reference to Dr. Winnicott's letter in your issue of Dec. 25, which has just reached me, the views of one who has used electric shock therapy in private practice in addition to psychotherapy may be of interest. As yet I am in the dark as to how electric shock works, but I do know to some extent what it does. In general, it has every appearance of acting primarily as a powerful and prolonged general tonic, so marked that it will rejuvenate to the extent of removing the ravages of several years (plus anxiety signs) from a paranoiac without in such a case altering the ideas one whit. I consider that it does this through a stimulation of the pituitary gland, and an indirect further stimulation of the whole endocrine orchestra, easily seen in the frequent upset of the ovarian rhythm. Acting on this view I have recently used subconvulsive doses, giving two or three at a time, with a total result in suitable cases as good as if convulsive doses are given.

I consider that heavy dosage may produce further effects—possibly fracture of the physical associational fibres in the frontal area. In some cases this may be of value, when a

patient is unwilling or cannot afford to undergo a prolonged course of psychotherapy, and in which treatment the association tracts of unhappy childhood may be "leucotomized." After due warning to the patient that such treatment is a surgical operation, I have attempted this twice, once with apparent success.

In general, I try to reserve electric shock for the middle-aged depressive, whose state is of physical origin, and only give it on occasion in the course of a session of psychotherapy as a physical tonic, making it quite clear to the patients that it will make them "feel" better in body and give them more factual energy, but that it will not alter the "feelings" of their minds in the least, which must be worked through and made fully conscious in the ordinary way. I quite agree that giving it to a child smacks of barely unconscious sadism.—I am, etc.,

Dublin.

L. F. DONNAN.

SIR.—As the result of analytical observations (using the method of analytical psychology) I am able to support Dr. Winnicott's statement; the process at work in shock therapy, from the patient's standpoint, is essentially akin to suicide, though, of course, actual suicide does not occur. The method of analytical psychology is different in many respects from that of psycho-analysis, so that it is a striking fact that two people using different methods arrive at almost identical conclusions.

I should like to point out that our view, derived as it is from the detailed study of individual cases, receives the strongest support from the reported efficiency of shock treatment for depressive cases, in which real suicidal impulses are common. If this conclusion be correct it would be extremely difficult for psychiatrists using shock treatment to see what is going on when the shock is applied, because they are participating in a method whose aim is to prevent the necessary information being revealed. Naturally these psychiatrists would deny the possibility of suicide coming into the picture at all. This has actually been demonstrated in your correspondence.

It is certainly bad psychiatry to use shock therapy as it is being used to-day, and the ethical question cannot be brushed aside in the cavalier fashion which some of your correspondents assume.—I am, etc.,

Nottingham.

MICHAEL FORDHAM.

### Significance of Dysphagia in the Psychopathic

SIR.—In the article describing a case of conversion hysteria v. Dr. Ranyard West (Nov. 27, p. 676) there are several points in the case which I think are worth further explanation. In spite of the extremely psychopathic history which the patient showed, may I ask if the diagnosis of myasthenia gravis was ever considered in this case? In the early part of the history it is stated that the patient could drink fluid in the morning, though not easily, but later in the day the fluid went the wrong way. This dysphagic symptom is extremely suggestive of myasthenia gravis, where muscular effort becomes increasingly difficult as the day progresses. We also know that in myasthenia gravis there are normal remissions of the disease which might account for the improvement of the patient with psychological treatment. The fact that the analysis took forty sessions seems to imply that the treatment took a long time to become effective.

Recently I have seen a case of a girl who was considered as a psychiatric problem for three years, whereas, in actual fact, she was a clear-cut case of myasthenia gravis. One psychiatrist had missed the myasthenic facies, and considered she showed the typical *belle indifférence* of the hysteric. The fatigue which she complained of was also put down as a neurotic symptom. It is true that in the early stages myasthenia gravis can be extremely difficult to diagnose, particularly differentiating it from a hysterical condition.

I do not say that Dr. West's case was one of myasthenia gravis, but certain points in the history are rather suggestive. I would also add that I consider dysphagia to be a very rare hysterical symptom.—I am, etc.,

M. CAMPBELL,  
Squadron Leader, R.A.F.

### The Mosley Incident

SIR.—Now that the conditioned release of Sir Oswald Mosley from detention under 18B has lost its sensational news value it may not be improper to consider those of its aspects which are of interest to the medical profession. They are two in number: one relates to herd psychology and the other to constitutional and ethical procedure.

**Herd Psychology.**—The "patient" in this case is a private citizen with a private citizen's rights, including that of entertaining and maintaining his own political faith. This country is at war with nations who contest that right and who do all in their power to suppress it, and it is largely to maintain what we believe to be an individual freedom of faith that we are fighting. But owing to the war it became necessary to prevent the patient from actively spreading his gospel without interfering with his freedom of faith and without any intention of inflicting punishment. A large proportion of the herd became confused in their reaction to the conditioned release of the patient, and showed by their behaviour and by their written and spoken word that his punishment by severe suffering or even by death was the object of their desire. And, as is not unusual, the herd instinct may be described in this instance as quite illogical and indefensible.

**Constitutional and Ethical Procedure.**—The patient, being ill, had a right to medical advice, and his medical advisers, strengthened by the opinion of eminent consultants, reported that his health and perhaps his life would be endangered by further detention. At this point a question arises which is one of constitutional and ethical importance. Has this patient also lost his right to professional secrecy in regard to the nature of his malady? And further, if he had not lost it, did he attempt to exercise it? The nature of the patient's malady and the treatment prescribed were publicly disclosed, whether with or without the doctors' consent we are unaware. At any rate the disclosure gave rise not only to uninformed and hysterical criticism in the Press but to ignorant and foolish questions in the House of Commons. In both instances a lamentable ignorance on the part of the public was brought to the surface. A doctor's responsibility is not only to treat his patient's local disease but to treat his patient as a whole.

We may hope that no further incident of this kind may happen, but we may justifiably ask for an authoritative statement in reply to the constitutional and ethical questions which I have raised. Without prejudging the issue I would suggest that the medical report given to the public would have satisfied all legitimate demands if it had contained only words to this effect: "In our opinion the health and perhaps the life of Sir Oswald Mosley will be endangered by his further detention."—I am, etc.,

Oxford.

E. FARQUHAR BUZZARD.

### Vulvovaginitis in Children

SIR.—In his article on the treatment of gonorrhoea in the female Brig. Osmond has necessarily given a restricted account of vulvovaginitis in children, but I regret that he has not stressed the importance of in-patient treatment under the best hygienic conditions. Many of these children come to us in a depressed state of general health, infested with vermin, and with impetigo and other skin diseases. A survey of admissions since 1939 shows that only 48% were found to be gonococcal before or after admission, so that the majority of vulvovaginitis infections under 10 years of age are due to other organisms—e.g., the staphylococcus, *B. coli*, streptococcus, etc.—and the primary lesion is usually found in a site other than the genital tract. Frequent bathing, good food, fresh air, and regular discipline do wonders for these children, and without such an improvement in general health no chemotherapy can give the maximum results.

In our experience gonococcal vulvovaginitis that is not sulphonamide-fast is best treated with sulphadiazine, as (in our hands) no toxic manifestations have been observed, such as may occur with the routine administration of sulphapyridine and (to a lesser degree) sulphathiazole. Resistant infections (and a relatively large proportion of such are sent for admission subsequent to failure as out-patients elsewhere) are notoriously difficult to treat. Encouraging results are being afforded by the local application of penicillin filtrate, but

restricted supplies do not yet allow of dogmatism. In the present state of our knowledge it would appear to be wisdom for all gonococcal vulvovaginitis infections to be considered as individuals and for no empirical treatment to be given as a routine measure. Furthermore, emphasis must be laid on the necessity for keeping these children under close observation for at least six months after the initial infection. Only thus will "relapses" be avoided and the danger of spread to other children in the home or the school be eliminated.—I am, etc.,

London, W.1.

G. M. SANDES.

### School Medical Service

SIR.—Dr. Ganlin's letter (Jan. 15, p. 90) would appear to be based upon a misunderstanding of the Education Bill. Were the position to be as he envisages it, then I fully agree that the results would be disastrous. The present routine cleanliness inspections are, however, carried out under the powers given by Section 122 of the Children's Act, 1908. This section it is not apparently proposed to repeal. It would appear to follow that the powers given by Section 52 of the Education Bill are supplementary to those already possessed and not in substitution thereof, which is a much more satisfactory position, though I doubt, personally, whether the proposed new powers will prove in practice to be of much use, since only cases of gross infestation are likely to come to the notice of the teachers.—I am, etc.,

A. C. TURNER,  
Senior Medical Officer,  
City of Leicester Education Committee.

### Nightwear for the Troops

SIR.—I was amazed recently at the information given me by the wife of an A.C.2 that no provision of nightwear is made with the uniform. Further, an application for coupons to make good the deficiency was refused on the grounds that it was unnecessary. If this is the official policy in such ranks of the Services I am concerned, not as was my informant that those who refuse to lower their standards must provide nightwear at their own expense and that of their family's coupons, but that those with low standards receive no encouragement to raise them; rather they have the official seal set on them. One of the revelations, brought to light by evacuation, of the low standards of personal hygiene prevalent in the population was the absence of nightwear. In *Our Towns*, which so admirably surveys the many deficiencies found, one of the suggested remedies lies in adequate education. For many years, of course, health visitors and teachers have worked along these lines, but have been handicapped in part by ignorance that certain habits existed; and they in common with others were shocked when the closer contacts of evacuation showed them up. If every child spent a period at a residential school he would learn certain principles of hygiene by putting them into practice which he would never learn from blackboard instruction; but even if this were possible it would not be until the next generation that the full effect could be felt, whereas there is, in the masses of young adults now under discipline in the Services, a good field for practical health education.

Perhaps in some directions the opportunity is being used and the question of nightwear may seem relatively unimportant, but is it not true that such a simple process as changing the clothes helps to keep down the parasite population and thereby mitigate the disease and discomfort caused by parasites? In modern warfare there will inevitably be large numbers of men stationed permanently well behind the front line, and it is surely not necessary for the same standard to be applied to them. What do the medical officers to the Services think, or are they not consulted in such matters? I believe these remarks do not apply to the women's Services, so why the sex differentiation?—I am, etc.,

Leicester.

JANET M. DONE.

### Prostigmin in Delayed Period

SIR.—Dr. E. Friedmann, in the *Journal* of Jan. 1, suggests that prostigmin should be tried "in all cases of delayed period except those of endocrine origin and those in which pregnancy has been established." He classes as "unsuitable patients" those with "obvious endocrine disturbances, a history of long-

standing amenorrhoea, or obvious menopausal symptoms," and relates that he has treated nine such patients "unsuccessfully."

What does he mean by "obvious endocrine disturbances" or "obvious menopausal symptoms"? The fact of the endocrine disturbance or menopausal symptoms being obvious or not depends only upon the powers of observation of the observer; the word "obvious" has nothing whatsoever to do with the condition of the patient and cannot describe it. What is obvious to one person may not be so to hundreds of others, and because a particular doctor does not notice a disturbance it does not mean that a disturbance is not present.

I would like to draw the attention of your readers to the fact that no good can result from Dr. Friedmann's recommendation that prostigmin be administered in "the treatment of delayed period," though they will possibly succeed in lulling their patients into a false sense of security if they act upon it.

He says that the drug should not be "tried where pregnancy has been established," yet in 30 out of his series pregnancy was the cause of the "delay"; pregnancy was "later discovered on clinical or biological investigations or the patients were known to be pregnant." Why does he recommend to others a procedure different from the one he himself has adopted? "Pregnancy," Dr. Friedmann says, "is not disturbed . . . prostigmin is safe . . . there is no tendency of the drug to interfere with the course of pregnancy." How is Dr. Friedmann to know that pregnancy has not been disturbed in some of his "successful cases"? It would seem beyond his power to establish a diagnosis of pregnancy in "a case of delayed period" without resorting to a "wait and see" policy or to help from laboratory tests.

He records that 24 of his cases were "poorly selected." Did he select them, and if so, why? He injects sterile water into 10 women: he observes, "No bleeding occurred." These cases must have been properly selected! For what reason does the injection of sterile water here prevent the menstrual flow? There is no reason why even a "delayed period" should not appear after such an injection, but in his cases the period obligingly waits for the "proper prostigmin course" which followed.

His experiments prove nothing and help nobody, and one wonders what ultimate good Dr. Friedmann hopes to have done by them. Should it not be the doctor's foremost endeavour first to decide whether the "delay" has occurred in the course of a harmless physiological process, or as a symptom of maladjustment leading to displacement and undue pressure on vital organs? Dr. Friedmann does not give any evidence that he even thought of assessing the influence of faulty functioning in his "diagnosis," which, therefore, was not a full and reliable diagnosis.

Is it not reasonable to consider and establish first the cause or causes, to ask first why a woman has a delayed period? Is it not misguided to produce the period at all costs, to "try prostigmin" and to proceed with "further clinical work to reveal the interesting effects of prostigmin in cases of dysmenorrhoea"? Dr. Friedmann will not find the means whereby to alter faulty functioning among the multitudinous variety of drugs on the market to-day, and though he may produce the period he does not put right the cause of the delay in such cases. And before proceeding with further useless experiments and recommending others to do likewise he would do well to become conversant with the work of F. Mathias Alexander, whose approach to all problems is first to establish beyond doubt the cause or causes, and who has provided a technique by means of which problems of faulty functioning can be solved.—I am, etc.,

London, W.1.

DOROTHY S. RADCLIFFE DREW.

### Heroin in Labour

SIR.—Dr. James Ross (Jan. 8, p. 59) expresses a view with regard to the safety of heroin in labour which is in conflict with pharmacological findings and recorded clinical experience in respect of this drug. That a drug stated to be five times more depressant to the respiratory centre than morphine (Dilling, *Materia Medica*, 16th ed.) should have this remarkable degree of safety in labour calls for some comment.

Favourable reference is made to heroin as an analgesic drug in labour in Williams's *Obstetrics* (7th ed.), where a dosage of 1/12 gr. is stated to have "no deleterious effect upon the child

providing the drug has not been given during the three hours preceding delivery." Clark in *Applied Pharmacology* (6th ed.) states that heroin "is in no way safer than morphine," and refers to heroin as being about 10 times as toxic as morphine. Heroin was introduced by Dreser in 1898. If Dr. Ross is correct in his estimate of its value in labour it is indeed remarkable that recognition of the value of heroin in this respect has been so long delayed.—I am, etc.,

Turriff, Aberdeenshire.

A. T. FORBES.

### Diet and Peptic Ulcer

SIR,—I am afraid that Dr. Maurice Webster has misunderstood Sir Arthur Hurst's meaning. One may disagree with Sir Arthur's speculative theories, as I do, but his factual observations cannot be assailed. I sympathize with Dr. Webster, but however hot his hyperchlorhydria may feel, a cold impersonal approach must remain the basis of all scientific investigation.

It is a practically daily observation, which is not sufficiently appreciated, that although hypochlorhydric patients are temporarily relieved by alkalis, their cure depends entirely on the administration of sufficient hydrochloric acid. "Heartburn" is a most deceptive symptom, and easily misleads the unaware practitioner, because his whole attention is focused on HCl as the cause of peptic ulcer. All authorities agree that HCl by itself cannot produce the ulcer. My own view is that hyperchlorhydria is the first manifestation of the pre-ulcerative stage. All foods give a quantitative physiological secretory response. It will surprise many of your readers that gastric stimulation of water gives a positive response (Rehfuß *et al.*). The important point, however, is to discover what happens when the stomach is empty, for it is at that moment that the sufferer becomes aware of his symptoms. Whenever the stomach contracts it produces acid, but why should the stomach contract so violently when it is empty even a long time before any signs of chronic ulcer become apparent? The most likely explanation is that it reacts to some form of irritation, probably local. My explanation is that this occurs when the normal mechanics of the intestinal tract are upset—i.e., when iso-peristalsis is interfered with—by one cause or another. All the trouble begins from that moment. The implications of this thesis, however, are too complex to be dealt with in the short space of a letter.—I am, etc.,

London, W.1.

J. JACQUES SPIRA.

### Riboflavin in Hereditary Syphilis

SIR,—Recent articles in the *Journal* have shown the importance of the vitamin riboflavin as a therapeutic agent in inflammations of the eye and skin found in acne rosacea and also in cases resembling pellagra. In the keratitis associated with acne rosacea blood vessels and infiltrates are found in the superficial part of the cornea and, in aggravated cases, ulceration. The beneficial effect of riboflavin in rosacea inflammations of the eye has been known for several years; but it is not so widely known that this vitamin has also a curative effect in interstitial keratitis due to hereditary syphilis. Interstitial keratitis is characterized by the ingrowth of adventitious vessels into the substantia propria of the cornea as well as infiltration of cells. The following two cases show that riboflavin may be a therapeutic agent by itself.

**Case 1.**—A youth aged 18 attended the out-patient department of the Chelmsford Hospital with a keratitis accompanied by circum-corneal injection. Slit-lamp examination showed the lesion to be situated in the substantia propria of the cornea. No mention is made in the notes of corneal vessels. Wassermann and Kahn tests proved negative. Treatment by atropine and ascorbic acid failed to cause any improvement; sulphonamide tablets did not help. Carious teeth were extracted without avail. On Oct. 2 riboflavin (1 mg. t.d.s.) was substituted for the ascorbic acid. Compared with the former treatment it acted like a charm. On Oct. 16 the circum-corneal injection had disappeared as well as the corneal opacity. Shortly afterwards he joined the Army, having passed his medical tests.

**Case 2.**—A girl aged 13, sister of the patient in Case 1, attended the clinic on Jan. 20, 1943, both eyes having been affected by interstitial keratitis of several weeks' duration. The case was typical. There was photophobia and lacrimation. Both eyes showed the typical salmon patch due to corneal vascularization. Corneal opacity and iridocyclitis were present. Teeth were typically Hutchinsonian. Wassermann and Kahn tests were positive. The

cause of the lesion in the brother's eye was now apparent. As he was several years older, the toxin had become more attenuated, the W.R. negative, and he showed a much milder corneal lesion. As riboflavin had caused such a marked effect in his case the same treatment was given to the sister. Notes record that on Feb. 20 the eyes were free from corneal injection. Later a complete course of novarsenobillon was given combined with riboflavin. Slit-lamp observation on Nov. 5, 1943, showed the cornea free from infiltrates and the corneal vessels represented by a few hair-like lines.

I ought to mention that in a case of acquired syphilis with deep vascularized keratitis and severe iridocyclitis in one eye treated by arsenical injections, riboflavin as an adjuvant did not appear to help. In the case of a young man with a vascularized keratitis of unknown origin, where the W.R. was negative and where syphilis could be excluded, riboflavin did not afford the expected improvement.

Will riboflavin prove a remedy in other manifestations of hereditary syphilis? In acne rosacea the ophthalmologist watches with interest the improvement which the administration of the vitamin effects in the skin of the face. In like manner the syphilologist may find a use for riboflavin in his department.—I am, etc.,

Chelmsford.

S. G. CORNER.

### Spontaneous Hypoglycaemia

SIR,—In your issue of Dec. 11 Dr. R. D. Lawrence expresses the view that spontaneous hypoglycaemia as an explanation for many minor indispositions has been overdone recently. Dr. Luntz, while supporting Dr. Lawrence, states that both hyper- and hypo-glycaemia are but "symptoms," but he rightly emphasizes that the nervous type of hypoglycaemia is a different phenomenon from that of hyperinsulinism, which term should be reserved for islet tumours of the pancreas. However, this statement, which suggests that the level of sugar in the blood is a "symptom," is one to which exception must be taken. Hypo- or hyper-glycaemia of itself can surely never be a symptom. The symptoms in neurotic patients to which Dr. Luntz refers are inevitably the reactions of the patients' nervous system to hypoglycaemia—if levels above 70 mg. per 100 c.cm. B.S. should be called by this name.

There is now evidence that individuals with cerebral dysrhythmia (about 10% general population and 26% of psychoneurotics) are particularly susceptible to lowering of the blood sugar, even to normal fasting levels. We have reported such a case, in which the electro-encephalogram (E.E.G.) was unstable below 100 mg. per 100 c.cm. yet stable above this level (*Lancet*, April 24, 1943). In these cases the symptomatology should not be regarded as purely hypoglycaemic, but as due to the increase of cerebral dysrhythmia which occurs. Our findings show that the normal E.E.G. does not exhibit instability at levels of blood sugar above 40 mg. per 100 c.cm., while dysrhythmics become unstable at higher levels. It has long been known that the onset of hypoglycaemic symptoms, as well as the onset of coma (Fraser, R., MacLay, W. S., Mann, S. A., *Quart. J. Med.*, 1938, 25, 115), are not related to any one level of blood sugar, and vary from individual to individual. No doubt constitutional abnormalities of electrocortical stability are among the factors determining these differences.—We are, etc.,

### Chemistry of Vitamin Therapy

SIR,—The articles on vitamins in the *Journal* of Jan. 15 show, if I may say so with the deepest respect, a lack of appreciation of the chemistry and functions of these bodies. The addition of 25 mg. ascorbic acid to the diet of any person who already has enough can make no difference. If Prof. Davidson had first estimated the urinary excretion of vitamin C, and then confined his treatment to those whose excretions were below the minimum physiological standards of Harris, the recorded results would have been different. Similarly with the case of the compound vitamin capsule: what good can a jumble of vitamins do if the recipients are already taking a sufficient diet?

The weakness of both these experimental groups is that the individuals were all apparently well. My colleague and I offered for your acceptance some months ago a series of 600 analyses where the vitamin C excretion had been estimated

by Harris's three-hour technique, and which showed a significant difference between the apparently well and the sick; whereas the well averaged comfortably above Harris's line, the sick were consistently below it. So any addition of vitamin to the well cannot have any demonstrable effect. Vitamins are not fuel; they are catalysts whose presence is necessary for metabolism, but an excess of catalyst will not increase the magnitude of the chemical reaction.—I am, etc.

GRIFFITH EVANS.

### The Rocking Stretcher

SIR.—Judging by the descriptions of rocking stretchers published in recent numbers of the *Journal*, there must be a competition to design some device or pivot to allow ordinary stretchers to be rocked. Mechanically these inventions are ingenious, and no doubt give great satisfaction to their inventors. Unfortunately, however, a rocking stretcher is intended for the resuscitation of the drowned or otherwise unconscious patient who is not breathing. I wonder how many of the inventors have considered the difficulty of safely securing an unconscious patient, who is limp and lifeless, to a rocking stretcher. To practise with a conscious subject is easy, but to fasten a toneless body on to a rocking stretcher by tying the ankles and wrists to the stretcher pole, as some inventors seem to consider satisfactory, is to court disaster. Serious damage to the limbs would be the least result, and I can imagine fractures of all types, even of the cervical spine.

I have recently had the experience of endeavouring to resuscitate an electrocuted girl of medium height and weight by means of a rocking stretcher. From this I can say that unless a proper brace, fitting between the patient's legs, dividing and fastening over the shoulders (similar to that provided on stretchers manufactured by Messrs. Siebe Gorman), is employed to keep the patient in position, an unconscious patient who is limp and flaccid would very quickly slide off the stretcher.

The inventors of rocking stretchers would be surprised to find how difficult it is to keep an unconscious patient safely fastened on to a rocking stretcher. Perhaps before any further methods of pivoting stretchers are invented they would do well to pause and consider this point.—I am, etc.,

Southwell, Notts.

### Cleansing Gas-contaminated Persons

SIR.—In the *Journal* of July 17, 1943 (p. 81), you published an article by Dr. Pollok Donald on a new method of gas training, together with a diagram illustrating a miniature gas-cleansing station. I entirely concur with Dr. Donald as to the apathy with which this subject is treated. If this apathy did not exist your correspondence columns would be full pointing out Dr. Donald's glaring mistake. It may be that he intended this to be so in order to gauge this apathy, as he says that his object is "not to instruct but to show how instruction may be given in a way acceptable to all concerned." His object is good but his diagram is dangerous.

If Dr. Donald is a gas instructor he should have read the official handbooks, in which case he would hardly have put his eye douche in the third compartment from the entrance to the station. This is most important, and the immediate treatment of blister gas in the eyes should be stressed to everyone in the country. The basis of all training is common sense, and this applies especially to anti-gas training. If anything falls in the eye obviously the first thing to do is to remove it mechanically. With a liquid, equally obviously the way to do this is to wash it out with large amounts of water. Applying common sense, the water should be warm to prevent spasm. As blister gas begins its foul work immediately it is only common sense to remove it at once. The penalties for delay are painfully obvious.

What happens in the gas-cleansing station in the diagram? The wretched patient arrives in a panic suspecting blister gas in the eye. Is his eye washed out at once? No. He has to go through endless formalities with labels, string bags, etc., and eventually is persuaded to have his outer clothing removed. He then goes through an air-lock, and entering another compartment is reduced to his birthday suit. Still clutching his

valuables, which have been horribly in the way of undressing, he enters yet another compartment, where he joins the queue for the eye douche (singular). The proper place for eye douches (plural) is at the reception ("dirty") end of the gas-cleansing station, and liquid gas in the eyes must be attended to at once. It is advisable to have a store of anti-gas ointment in the "dirty" end. This is not marked on the diagram, but is doubtless not overlooked in practice. And this reminds me, every family should have a stock of anti-gas ointment (preferably No. 5) in good condition.—I am, etc.,

F. PITT PALMER.

Cmndr., R.N. (ret.)

### Treatment of Coryza

SIR.—Adverting to Mr. Carew-Shaw's letter (Dec. 25, 1943, p. 830) regarding the treatment of coryza with ephedrine and argyrol in normal saline, I would like to point out that it appears to be quite beyond the ordinary pharmacist's facilities to produce a stable solution of these components. Undoubtedly many doctors will have been interested in Mr. Carew-Shaw's advice, and I feel that they should know that a stable solution is apparently only available in the form of a proprietary product. Unless this is made clear others will prescribe argyrol, ephedrine, and normal saline, as I did, only to find that a precipitate appears almost immediately, and that the resulting unstable solution causes congestion and crusting of the nose, as Mr. Carew-Shaw has observed.—I am, etc.,

London, W.I.

A. PINEY.

### Fact and Fancy in Poliomyelitis

SIR.—My attention has been drawn to the leading article in the *Journal* for July 31, 1943. This is in part a review of the book published by the Bruce Publishing Company, St. Paul, Minnesota, and presented by Dr. J. F. Pohl and myself, with the foreword written by Dr. Frank Ober, professor of orthopaedic surgery, Harvard University, and commentary by Dr. Miland Knapp, professor of physical therapy, University of Minnesota.

At the onset you state: "It is permissible to regret that Sister Kenny was not content to remain an outstanding practitioner of her particular art, and that she succumbed to the temptation to rationalize her methods by providing a scientific basis for them." I may here emphatically emphasize the fact that there was no one on earth more content to pursue the even tenor of my way than I, right from the onset in my early Australian days, and that all my activities have been by special request. The public presentation of my work in Australia was made by special request. My visit to the United States was arranged by my own Government and a group of medical men in Australia, who wrote to the senior orthopaedic surgeon of the world-famous Mayo Clinic. My association with the University of Minnesota was made by special request. My association with the University of New York was by special request. My position as honorary director of the Elizabeth Kenny Institute was accepted by special request.

You say that I have formulated an entirely new concept of the disease. This is also the opinion of all medical observers. It was first published by Dr. Wallace Cole, professor of orthopaedic surgery, and Dr. Miland Knapp, professor of physical therapy, University of Minnesota, in the *Journal of the American Medical Association*, June 7, 1941. In this paper they state that the concept of the disease is entirely the opposite of that previously recognized, and this new concept had been proven in 100% of cases. This is also the opinion of Dr. Frank Krusen, professor of physical therapy, Mayo Clinic, published in the paper presented in the *Staff Bulletin*, Aug., 1942. In this paper Dr. Krusen admits that he thought I was unbalanced when I arrived in the United States and presented my ideas, but added that he admitted "she has presented to us an entirely new concept of the disease anterior poliomyelitis and a satisfactory treatment for this concept." Before my arrival in the United States the percentage of recoveries according to statistics published in the *Journal of Bone and Joint Surgery*, Oct., 1941, was 13. Since my arrival in the United States the recoveries are 88%. I have also been requested to assist in preparing a book on the muscle physiology and function. This is now in operation.

I am quite sure that if your Association could see its way clear to send a suitable physician to Minneapolis we would be in a position to present sufficient evidence to prove that the old concept of the symptoms presenting themselves in this disease was incorrect. I am also happy to say that I could prove to him that there is a certain condition existing in this disease which indicates that portion of the body in which the disease is likely to attack, and by the prompt administration of treatment the progress of the disease can be arrested in a great many instances. It has also been acknowledged that the physical therapy procedures introduced by me have proved most advantageous in other types of neuromuscular injuries and war wounds.

I quite understand your criticism. As a matter of fact it is extremely mild in comparison with the criticism I first met with in this country by those who now strongly support my work. Therefore I would very much appreciate the publication of this explanation.—I am, etc.,

Minneapolis.

E. KENNY.

### Photomicrography with Ordinary Cameras

SIR,—I was much interested in the article on photomicrography with ordinary cameras by Dr. W. N. Leak (Dec. 18, p. 787), and would like to point out that colour photomicrographs and the method of taking them with ordinary cameras were demonstrated by me at the Dermatological Section meeting of the Royal Society of Medicine held in London on March 19, 1942, when I showed colour photographs and photomicrographs of sections of two rare skin diseases.

The method of taking colour photomicrographs without the use of any special apparatus is as follows: "The section is placed and focused under the microscope in the ordinary way, then the microscope with the slide in position is tilted into the horizontal position and the reflector adjusted to give good illumination. The miniature camera, a Zeiss Ikon, is brought up to the ocular of the microscope in the same horizontal plane till it just touches firmly. All extraneous light is excluded by means of some suitable covering—e.g., a piece of dark cloth wrapped round the junction. Film used was Kodachrome A (for artificial light). One photoflood light was used and reflected as described above. The camera lens was set for infinity, the aperture used was  $f/3.5$ , and the exposure was one-fifth of a second. One-tenth of a second was also tried, under the same conditions, but was not sufficient. I hope to make further trials of this simple method of taking coloured photomicrographs as it does not require any special apparatus" (vide *Proc. roy. Soc. Med.*, 1942, 35, No. 4). I might add that the colour photomicrographs referred to above were shown in the scientific and technical section of the 1943 Annual Exhibition of the Royal Photographic Society of Great Britain in London.

Colour photomicrographs are very much more interesting to look at, and lend themselves as an ideal means of projection lantern for demonstration at meetings, etc.—I am, etc.,

Leicester.

F. A. E. SILLCOCK.

### Emulsions

SIR,—May I suggest that there is another aspect of emulsions than that mentioned by you on Dec. 18 at page 803, one which is really of great importance to practical medicine, though it is seldom considered. The work is very old. So far as I remember, Pickering, in the last century, showed that a solution of phenol in water might have little disinfecting power; but if an emulsion of some inert oil, or very fine inert solid particles, were added the bactericidal power was increased. This was followed by many others, and, so far as disinfectants go, gave rise to those with "high coefficient."

There is a boundary between a drop of water in oil or of oil in water. This boundary is due to electric charges—molecular attraction, if that term is preferred—which cause the drops to be round, and which also include surface tension phenomena. The less the diameter of the drop the greater the force per unit area; so that when the diameter is extremely small the force is comparatively very great. The explanation of Pickering's work would be that the molecules of phenol are attracted to the interface, so that the concentration per minute area is very great; whereas the concentration per c.c.m., say, is comparatively small. The bacteria also have charges

on their boundaries, and are also attracted to that interface (oil-water), so that they are exposed to the comparatively strong concentration of phenol there.

This subject is a very large one and concerns many things in medicine, such as the function of the blood corpuscles, tissue cells, and so on. The odd thing is that, although it is mentioned in textbooks on physiology, it seems to be completely ignored in practical medicine; yet it is of much importance in that sphere.

Dealing with dermatology, I should say that the subdivision of the remedial agent increases its "potency," because the charges at the interfaces will react with charges on the prickly cells, or on the prickles themselves; so that in the first case there will be stronger reaction between the agent and the cells; in the second, the agent will be able to pass more readily between the prickles and affect the cells underneath. The result might be a variation in the outermost cells or in those below them. I know of no proof that the prickly cells have a charge, but they are chitinous, and there is definite proof that emulsions wet chitin more readily than water—the nail, for example.

The "value" of an emulsifier will depend on its ability to reduce the oil (to use popular terms and not phase-theory terms) to extremely minute drops; and that is why some of the modern emulsifiers are more useful. So the "value" can be estimated by such determinations as the surface tension, number of globules, opacity, and so on. The detergent effect of soaps is due to this property—it is really a fine emulsion. A solvent will wash away a greasy mark on the skin by dissolving the grease, and often substances from the cells of the skin. A soap acts by emulsifying the grease so that it is washed away with the dirt by plain water. If the soap is alkaline it will also affect the cells; if it is superfatted it will tend to supply some fat to the cells (it also annuls the alkalinity of the soap due to dilution).

All this business of charges, etc., is very intricate and requires a good knowledge of mathematics. But it is not necessary for the practitioner to know that: only that he shall understand the results and be able to apply them in practice. So I suggest that there is really great scope for some medical man who is lucky enough to know sufficient maths. to write up an account of it—as to how, when, and where it may affect practice. For instance, it must be concerned in the problem of feeding and digestion of milks; for the globules of fat vary in diameter and the protein adsorbed to the globules varies. One peculiarity concerns the dermatologist—namely, that there is evidently some practical difference between solutions, emulsions, and ointments. One can compare the effect of a "blob" of ointment containing, say, 30% of calomel with a solution of mercury biniodide 1 in 1,000, or more dilute as preventive against spirochaetes.—I am, etc.,

Kingston-on-Thames.

W. F. COOPER.

### Malaria among Troops in W. Africa

SIR,—Your leading article (Jan. 15, p. 84) starts with a most misleading sentence. Your writer can have little personal knowledge of the place or he would remember month after month of perpetual Turkish baths, with no possibility of a change to a better climate till his next leave was due. He would remember the thirst produced by this heat and the boredom after sundown, and would probably think that he had consumed more alcohol than was good for any man. Could he forget yellow fever? Malaria would have bothered him little more than influenza in an English winter. Malaria is a mere fraction of West African unhealthiness.—I am, etc.,

O. G. WILDE.

\* By "unhealthiness" in inverted commas was meant a reputation for unhealthiness. It was not intended to imply that there were not other causes of ill-health in the climate of the West Coast of Africa and other tropical countries. The statement was an expression of the writer's own experience of life in many tropical climates, and is, he believes, generally speaking, true. Probably it is the heavy mortality from black-water fever—the result of malaria—which has usually been responsible for the gaining of such reputations. Yellow fever was in the past, again as a result of mortality, perhaps in the New World an even greater originator of evil reputations, but at the present time things have greatly changed.—ED., *B.M.J.*

## Obituary

### MAITLAND RADFORD, M.D. D.P.H.

Dr. Maitland Radford, whose death at the age of 59 occurred on Jan. 19, was one of those excellent medical officers of health who are able to achieve the most satisfactory administrative results with the minimum of officiousness and dissension. This ability was due partly to his wide knowledge of public health and his very alert and progressive mind, partly to his tact, arising from a natural sensitiveness to the feelings and opinions of others; partly to his charm, which was assisted not a little by his keen but kindly sense of humour and ready wit; and partly to the conscientious and energetic way with which he pursued his objects without the slightest regard to personal ambition. In spite of his urbane and generous manner, and though the overriding of other people's opinions was so far from being a pleasure to him that it was often an obvious embarrassment, nothing would induce him to do or say anything which conflicted with what he thought was right. In respect of his principles he was adamant and fearless.

Maitland Radford was the son of Ernest Radford, a barrister who lived at Hampstead, and who was also a progressive thinker and a friend of Shaw, Wells, William Morris, and Bradlaugh at a time when many of their ideas, which are now commonly accepted, were regarded with suspicion and even with hostility. There is little doubt that this background of controversy in the cause of rational thought and action had a profound influence on Radford's outlook and character. He was educated at Abbotsholme School, Derbyshire, and completed his medical studies at University College Hospital, where he qualified in 1912. In 1914 he took his M.B., B.S. (London), and during the war joined the R.A.M.C. as a temporary medical officer and was posted to No. 3 General Hospital in France. Later he returned to complete his study of public health at the North-Eastern Fever Hospital and Queen Mary's Hospital, Carshalton, and during this period he married Muriel Ann Lloyd, also a doctor, and the daughter of Dr. Henry Lloyd of St. Asaph, Wales. In 1920 he took the M.D. in State Medicine and D.P.H. (London), and in March, 1921, was appointed assistant M.O.H. to the borough of Shoreditch, where, after promotion to deputy, he became medical officer of health in 1927. He is still remembered in that borough for his efficiency, his easy and courteous manner, and especially for the great interest he showed and the considerable improvements he made in the maternity and child welfare scheme.

But though Dr. Radford devoted much energy to his immediate work he was not a man to allow the local trees to obscure his vision of the public health wood—or, as he might have said, the public health jungle—as a whole. He took a deep interest in general problems of public health, particularly in housing and health propaganda. He was a founder-member of the Central Council for Health Education and had much to do with the inception of that important body. For many years he was its honorary treasurer, and at the time of his death held the position of vice-chairman. He was also an active member of the Society of Medical Officers of Health, which he joined in 1920 and in which he was president of the M. & C. W. Group in 1931-2 and president of the Metropolitan Branch in 1940-1. In 1934 he became M.O.H. of the borough of St. Pancras, where his many good qualities were speedily recognized. He was chairman of the St. Pancras Division of the B.M.A. in 1936 and again in 1943. In 1938 he was a vice-president of the Section of Public Health and Hygiene.

The work of an M.O.H. is not often of a very dramatic kind, nor do the general public for whom he works often appreciate or even realize what is being done for them by a capable man in his position. It is, however, no exaggeration to say that there is no member of his staff or of the borough council who will not regret the loss of his leadership and that he will survive in the minds of many, not only as a memory, but as a permanent influence on their thoughts and actions.

C. H. writes: Radford was, in the best sense of the word, an intellectual. Essentially humble, his scintillating mind leapt from idea to idea, flashing a light just long enough to make clear his point before the beam passed with amazing swiftness to yet another idea. It is surprising that he found satisfaction in an administrative life. One could picture him as a university don, as a teacher, for he was above all a thinker. In the Central Council for Health Education he was a fountain of ideas, prodding the conventional, flicking the timorous with a wit which was as kind as it was charm-

ing. His interest was in ideas and principles, and he could be passionate in their defence. A good treasurer, though he knew and cared nothing for accounts; an efficient vice-chairman, though procedure left him cold, he would have been chairman, and a great chairman, in a few months' time. He leaves a gap which cannot be filled.

### F. WILFRED WILLWAY, M.D., M.S., F.R.C.S.

We regret to announce the death on Jan. 6 at the early age of 36 of Mr. Francis Wilfred Willway, temporary assistant surgeon to the Bristol Royal Hospital and a former Hunterian Professor of the Royal College of Surgeons. He was the son of the late Dr. Frederick Willway of Streatham, and studied medicine at King's College Hospital, whence he qualified in 1930 after graduating B.Sc. (London) with honours in 1928. In successive years he took the M.B., B.S., the F.R.C.S., the M.S., and the M.D., and after working as surgical registrar and casualty officer at King's he became in turn senior house-surgeon at the Royal East Sussex Hospital, resident surgical officer at the Royal Manchester Children's Hospital, and assistant surgeon to the West End Hospital for Nervous Diseases.

#### Prof. GEOFFREY JEFFERSON writes:

British neurosurgeons deplore the death of Wilfred Willway. It is unlikely that any of us will again see such a combination of debonaire heroism and sound practical utility as his life showed, not paralleled even by Hans Zinsser, who had a shorter battle to fight and was an older man. Few people realize that death is close upon them, and none that I have known have treated the knowledge with Willway's good-natured disdain. Its gradual inevitability over a period of years failed to impair either his cheerfulness or his rooted determination to utilize to the full his many gifts in the service of his fellow men. He often spoke of his impending death and his determination that the knowledge should not deflect him from his duty. This was particularly evident at the height of the air attacks on Bristol, where he overdrove his ailing body. What was extraordinary about Willway was that he expressed no bitterness at the shortness of his days, no complaints that he would never see the fruition of his plans and dreams. None the less he accomplished a great deal. Some of his work cut into new ground (leucotomy), and he deserves great credit for his enterprise there, but he did also a great deal of solid work on more conventional lines. He had a brilliant, a mobile, intelligence and a great disregard for the sanctity of the opinion of his elders, from which all edge was removed by the knowledge that all that he had to say he said at once. And how entertaining he could be! We neurosurgeons cannot afford these losses from our ranks that the last three months have brought. Willway and Eden were a notable pair, and however time chances to fill the gaps those brave personalities are for ever lost.

#### A surgical colleague writes:

Wilfred Willway was one of the most brilliant students of King's College Hospital. He had that type of brain which makes its possessor able to play four games of chess and conduct a conversation at the same time. He never failed in any examination, took the F.R.C.S. (England) and M.S. (London) at an early age, and then the M.D. "just for fun," as he explained. He was a great teacher, whose students admired and loved him as did all his friends. As a man he was full of kindness and humility and yet charged with enthusiasm for his work and the welfare of his patients, students, and friends. Coming to Bristol from London, Willway entered fully into the teaching and professional work of the Bristol Hospitals and Medical School. He was a pillar of strength to the hospitals' staff, who, because of his sound organizing powers, gave him charge of the war emergency arrangements at the Royal Infirmary. Willway was Bristol's first neurosurgeon, and he was rapidly achieving a wide reputation for his work at the infirmary and the Burden Neurological Institute. He was particularly interested in the surgical treatment of mental disease and had performed more leucotomies than any other surgeon in this country. His papers on this subject in collaboration with neuropsychiatrists are highly important. For years he made a heroic struggle against the ravages of a remorseless chronic malady which from time to time laid him low, but each time he came up smiling again and would laughingly chat about the prognosis. His courage was admirable, and in the course of a long day's operating it is reported that on one occasion he fainted twice. His tall spare frame, high forehead, and rather prematurely bald head, with merry eyes behind his large glasses, were the introduction to a personality which was widely loved and will be sadly missed. He was on a plane above most people, and Bristol is a poorer place for his departure.

## G. H. PEARCE, M.D., M.R.C.P., D.P.H.

Dr. George Herbert Pearce, who died on Jan. 6, had been a member of the B.M.A. for 45 years. He was vice-president of the Section of Public Medicine and Industrial Diseases at the Bradford Annual Meeting in 1924, was chairman of the Dewsbury Division in 1931-2 and represented it at nine Annual Meetings, and became a member of the Insurance Acts Committee in 1936. He took the Scottish triple qualification in 1897, the D.P.H. of Cambridge in 1905, the M.D. of Durham in 1914, and the M.R.C.P. in 1935. His successor, Dr. W. J. Frajin, sends the following appreciation:

The death of Dr. G. H. Pearce removes one of the most prominent personalities in public health during this century. He had been M.O.H. for Batley for almost 30 years before his retirement 5 years ago. His great gifts of personality and ability soon began to be felt in his profession and his influence extended far beyond the boundaries of Batley. He worked hard to improve the status of the medical officers of health in the country, and those of us who belong to the younger school of M.O.s.H. owe a great debt to his untiring efforts on our behalf. He was an outstanding figure in the Society of Medical Officers of Health, serving as its president in 1932. He was well known at the Ministry of Health and was a friend of nearly all its leading medical officers. At Batley he produced a public health department which was probably second to none in the country. He was a gifted administrator, and as he was also a barrister-at-law his legal knowledge proved a great asset. He approached his problems fearlessly, the health and welfare of the people of Batley being his first concern, and with a stern sense of duty he attacked all obstacles. From his staff he demanded first-class efficiency. He was deeply touched when the Batley councillors combined to make him a presentation on his retirement, for he had the erroneous idea that he was not a popular man. He always contended that if an M.O.H. did his duty he could not expect to be popular with the community. Those of us who mix among the people of Batley know how much Dr. Pearce was respected for this quality of devotion to duty. During his retirement he did part-time service for the Ministry of Pensions at Leeds, a work which gave him great joy and satisfaction. He attended regularly the meetings of the Yorkshire Branch of the Society of Medical Officers of Health and was a very valued member, owing to his rich experience in procedure. He was ever ready to help the younger members of the profession with his wide knowledge and sane counsel. His fine Victorian courtesy of manner made him a charming companion socially, and this was particularly evident in his home.

## PROF. ALFRED VOGT, M.D.

Prof. Alfred Vogt, the famous ophthalmic surgeon and director of the University Eye Clinic, died at Zurich on Dec. 10, after a long illness, at the age of 64. He had resigned his chair at the university earlier in the year on account of ill-health.

Alfred Vogt was born in Switzerland on Oct. 31, 1879, and after studying at Aarau Gymnasium he went to the Universities of Basel and Zurich, graduating M.D. in 1902. There followed a series of house appointments, at the end of which, in 1909, he became chief resident physician at Aarau Hospital. There he was to spend the next nine years till his appointment as professor extraordinary at Basel, where in 1920 he was elected to the chair of ophthalmic surgery at the university. He was immediately put in charge of the research department, where he devoted himself with characteristic energy to the problems of senile cataract. He edited at this time Haefliger-Semich's popular manual, *The Pathology of the Lenticular System*. In 1919 he perfected the slit-lamp microscope, which is a binocular mechanism based on an optical system, for the focal illumination of the eye, as well as being responsible for the introduction of novel operative procedures into ophthalmic surgery. His celebrated *Text-book and Atlas of the Slit-Lamp Microscopy of the Living Eye* was published by Springer from 1921 to 1931. To facilitate the detailed examination of the retina he introduced infrared rays into ophthalmology, and, in order to study the true nature of snowflake and glassblowers' cataracts, he carried out experimental studies on the effects of various rays on the eyes. His subsequent researches, prosecuted with his usual thoroughness and enthusiasm, dealt with the healing of detached retinæ, with his discovery of glaucoma of the lens capsule, and with various forms of cataracts. In his investigations on the optical constants of the eye and on the crystalline lens he approached Helmholtz in versatility. In 1923 he was invited to assume the chair of ophthalmology at Zurich and the direction of the University Eye Clinic. It was from Zurich then that he achieved the widest international celebrity, though his basic work was done during his Basel years. He brought to the problems of ophthalmic surgery extensive knowledge of biology, internal medicine, and physics. As often happens to historic and popular figures, public attention has been focused on his skilful

operations, his brilliant technique, and the long pilgrimage of distinguished men who flocked to his clinic; but his fundamental contribution to medical science has been overlooked. However, in December, 1942, the Swedish Medical Society of Stockholm awarded him its most-coveted Gullstrand Medal, presented every ten years to the most distinguished ophthalmologists. We mourn with our Swiss colleagues the untimely death of one whose name ranks among the greatest of surgeons and whose work will long remain the embodiment of all that is best and noble in the traditional culture of Europe.

R. E. G. A.

Dr. RICHARD BEVAN LLEWELLYN, who gave long and faithful service as assistant medical officer under the Glamorgan County Council, died at his home at Llanishen, near Cardiff, on Dec. 1, aged 56. Fifth son of the late Alderman William Llewellyn, a former chairman of the Glamorgan County Council, he studied medicine at the University of Edinburgh and graduated M.B., Ch.B. in 1913, and later in the same year was appointed to the post he held until his death. During the last war Dr. Llewellyn served as a temporary captain in the R.A.M.C. in the Near East and Far East, and he joined the B.M.A. in 1917. He is survived by his wife.

Worcester and district has lost its leading ophthalmologist by the death after a short illness of Mr. BERNARD HAMILTON ST. CLAIR ROBERTS. He died at his residence near Worcester on Dec. 19. He had suffered from an infantile paralysis since childhood. St. Clair Roberts was the son of the late J. W. Roberts, L.D.S., of Dudley. He studied medicine at Mason's College, University of Birmingham, and was one of the senior prosectors in anatomy. He qualified M.R.C.S., L.R.C.P. in 1900 and was house-surgeon at Wolverhampton Eye Infirmary, senior house-surgeon at the West Bromwich District Hospital, and for three years house-surgeon at the Birmingham and Midland Eye Hospital. He was early appointed ophthalmic surgeon to the Guest Hospital, Dudley, and held that office until 1940, when he was appointed consulting ophthalmic surgeon. He came to Worcester in 1908 and was the first consultant to settle in the district. In 1911 he was appointed surgeon to the Worcester Eye Hospital, and he took a very active part in the work of that hospital right up to the time of his illness, only four days before his death. He was very largely responsible for keeping the hospital up to date, and was instrumental in acquiring new premises, when the work done made that an urgent necessity. He was beloved by all his patients, both rich and poor, and he was a true friend to them all. His opinion was widely sought by the medical practitioners in the district. He was punctilious in the performance of his duties at the hospitals which he served. He was ophthalmic surgeon to many of the education committees in the County of Worcester, and he had established an orthoptic clinic at the Worcester Eye Hospital. St. Clair Roberts had a most generous disposition and had no enemies. He had been a member of the B.M.A. for about 40 years, and in 1931-3 held office as president of the Worcester and Hereford Branch. He was a very active member of the Oxford Ophthalmological Congress and never missed a meeting; he was also a member of the Ophthalmological Society of the United Kingdom and attended meetings of other scientific societies. A memorial service held at the Worcester Cathedral on Dec. 23 was attended by many of his medical colleagues, friends, and patients. The address was given by the Dean of Worcester, who is president of the Worcester Eye Hospital. Mr. St. Clair Roberts leaves a widow and one son, who is studying medicine at Magdalen College, Oxford.—H. N. C.

Dr. FLORENCE SCOTT KIRK died suddenly on Dec. 22, while on her way to the Jessop Hospital for Women, Sheffield, to carry on her duties as pathologist. The daughter of Dr. Robert Kirk of Glasgow, Miss Kirk was born on March 8, 1889. She was educated at the Glasgow High School for Girls and at Glasgow University, where she graduated M.B., Ch.B. in 1915. She held resident appointments at the Royal Maternity Hospital, Glasgow, and the Royal Infirmary, Oldham, and in 1917 became a civilian medical practitioner attached to the R.A.M.C. In 1918 she was transferred to the 1st Eastern General Hospital, Cambridge, as pathologist, and when that hospital was closed in 1919 she was transferred to the Central Military Laboratory Medical Schools, Cambridge, as assistant pathologist. She left the Army service in April, 1920, and became junior assistant in the Pathological Institute of the Royal Infirmary, Glasgow, under Prof. Tschacher. Two years' work there was followed by her appointment as assistant pathologist to the Victoria Infirmary, Glasgow, where she worked for three years, and in 1925 was then appointed assistant pathologist to Sheffield University and the Jessop Hospital for Women. In 1923 she obtained the Cambridge D.P.H. For the past 18 years Miss Kirk has worked at the Jessop Hospital, and with the

passing of the years she was constantly enlarging her knowledge of gynaecological pathology, keeping pace with the many advances that have taken place during this time. Her work was conscientiously carried out. Her opinion on specimens submitted to her was carefully considered before being expressed. It was always sound, and was greatly valued by the hospital staff. There is no doubt that the fine work she has done for so many years was a most important factor in the success of the hospital practice. Apart from her medical work, Miss Kirk was greatly interested in social problems, and devoted much time and thought to them.

Dr. ALFRED JOSEPH PICKWORTH, who died in retirement on Dec. 23, aged 86, had practised for over half a century in the Lakenheath district of Suffolk. He came of a medical family, for his grandfather, two uncles, and a son have also been members of the profession. He was born in Lincolnshire and went to school at Bath, and studied medicine at Liverpool, qualifying as L.R.C.P.Ed. and L.R.F.P.S.Glas. in 1880. Four years later he went to Lakenheath, where he became not only the medical attendant and adviser of the people of his large practice but also took duty as a Methodist minister, and his medical and religious work were closely intertwined. Dr. Pickworth was prominent in local public life, a J.P. for Suffolk, and in 1935 the County Council advanced him from the position of a councillor to that of an alderman. He was a governor of Addenbrooke's Hospital, Cambridge, and for years attended the Mildenhall Cottage Hospital. On his retirement from medical practice a large gathering assembled to do him honour and make a presentation to him and Mrs. Pickworth. He was a member of the B.M.A. from 1881 to 1930, but took no part in medical politics.

We regret to announce that Dr. JOHN CHARLES WILLIAM GRAHAM, a well-known Cambridge practitioner, died on Jan. 1, aged 72. From Brighton College he went up to Trinity College, Cambridge, where he distinguished himself as a swimmer and member of the University water-polo team. Having taken the B.A. in 1893, he went to St. Thomas's Hospital for clinical study, qualifying in 1899, after which he returned to Cambridge as house-surgeon at Addenbrooke's Hospital. He worked for a time at High Wycombe and then returned again to Cambridge and set up practice, taking his M.D. in 1909. He was chiefly interested in ophthalmology and acted as clinical assistant at Addenbrooke's for many years, and also as consulting ophthalmic surgeon to the Huntingdon County Hospital. During the last war he served on the staff of the 1st Eastern General Hospital, retiring in 1919 with the rank of major, R.A.M.C.(T.F.). Dr. Graham was a member of the B.M.A. for over 40 years and took an active interest in its affairs. He represented the Cambs and Hunts Branch at a number of Annual Meetings.

By the death of Lieut.-Col. A. E. J. LISTER I have lost a life-long friend, writes Mr. J. Cole Marshall. We were at Dean Close School, Cheltenham, together, and then we both went on to St. Bartholomew's Hospital, where Lister passed all his examinations with ease, also taking the Brackenbury Medal—the blue ribbon of the surgical scholarships. Lister was also prosector at the Royal College of Surgeons. After graduating M.B. and B.S.Lond. he took his final Fellowship, passing this examination under age. He then decided to enter the Indian Medical Service, obtaining first place in the entrance examination and passing out first, being presented with the bronze medal for efficiency. Soon after starting his career in India Lister was attached to the 27th Punjab, and at the Battle of Jid Boli he rescued a wounded officer under fire when the stretcher-bearers had bolted; he not only saved the officer's life but continued his arm being amputated, thus allowing him to continue his career and eventually to become a general in the Indian Army. In this campaign Lister caught a fever which undermined his health for the rest of his career. I would especially like to dwell on his ophthalmic work. On returning from the campaign he was attached to the staff of H.E. the Commander-in-Chief of the Indian Army, Sir C. MacCreagh, and remained with him until 1913. During his leave he studied ophthalmology in Vienna under Prof. Fuchs, and also worked at Zurich and Paris; being very proficient in languages he naturally became well known in those universities. During these years he worked with Lieut.-Col. Henry Smith at Jullundur and Amritsar; he wrote an appendix to Colonel Smith's book on treatment of cataract by the intracapsular method, and also analysed the cases of vitreous loss in this operation. He also wrote a paper on conjunctival flaps and their use in the intracapsular operation. Lister was a good and quick operator and had a great experience in cataract. In 1913 he inaugurated the ophthalmic department of King George's Hospital at Lucknow. He first was appointed professor of physiology, and then, in recognition of the way he developed the ophthalmic depart-

ment, was made first professor of ophthalmology. In 1920, owing to the great increase of eye work, a new wing was in course of construction, but though Lister had hoped to return to India, in 1920 he had to retire from the I.M.S. because of ill-health. His ophthalmic work in India was greatly appreciated; he was appointed ophthalmic surgeon to two Viceroy's and was consulted by many of the leading Indian Princes and high officials. On his return to England Lister started consulting practice and was appointed assistant surgeon to the Western Ophthalmic Hospital, but in 1923, owing to ill-health, he went to Bristol, where he was attached to the Bristol Eye Dispensary, reorganizing the work of the hospital. He worked at Bristol for many years and had a considerable consulting practice. In 1933 he retired from his hospital work because of poor health, but still took a great interest in the institution. Lister was a wonderfully kind-hearted man, and well loved by all who came in touch with him, both in his private and hospital work. Considering his ill-health it was marvellous how he carried on for so many years. In ophthalmic literature his name was well known, as he contributed to the Ophthalmic Section of the *Medical Annual* from 1922 to 1930. Lieut.-Col. Henry Smith, I.M.S., writes: After Col. A. E. J. Lister's return from sick leave from Somaliland fever early in his career he was posted to Jullundur, where I first became acquainted with him. From cantonment to my hospital at Jullundur city was 3 to 4 miles. While there I invited him to come daily to my hospital and work with me in his spare time, which he took full advantage of. The variety of clinical material was unsurpassed in quantity and quality, with only one boss—myself. How he enjoyed the hard daily steady work! A true and loyal friend, an honest and courageous man, and the finest Christian I ever met. I mourn his loss.

## The Services

The *London Gazette* has announced the appointment as M.B.E. (Military Division) of Flying Officer Robert Dunlop, R.A.F.V.R., and the awards of the George Medal to Capt. C. E. L. Allen, S.A.A.F., and Flying Officer G. H. Dhenin, R.A.F.V.R., and the B.E.M. (Military Division) to Corporals C. V. Burton, R.A.F.V.R., and W. J. Lush. The announcements read as follows:

F/O ROBERT DUNLOP, R.A.F.V.R., and Cpl C V BURTON.

One afternoon in July, 1943, an aircraft crashed on landing and caught fire. The pilot and a passenger, who were the only occupants, were both thrown out of the cockpit and trapped beneath the wreckage of a wing. Cpl Burton, assisted by two other airmen, attempted to rescue the occupants, but all were driven back by the heat. Undeterred, Burton made another attempt alone, and this time succeeded in partially lifting the burning wreckage of the wing and he then dragged the pilot clear. F/O Dunlop, a medical officer, had arrived at the scene of the accident, and on being informed that the passenger was still under the wreckage, attempted to release him. While this was being done an explosion occurred, but F/O Dunlop continued his rescue efforts and dragged the passenger clear of the aircraft. This officer and airman displayed considerable bravery.

Capt COLIN ERNEST LEWER ALLEN, S.A.A.F.

One night in July, 1943, an aircraft, with a crew of four, collided with a stationary aircraft and two trucks when taking off. The bomber, which was carrying six 250-lb. bombs, burst into flames. Capt. Allen, the squadron medical officer, after instructing an orderly to bring a near-by ambulance to the aircraft, proceeded to the scene of the accident. Before he was able to get to the wreckage he saw one member of the bomber's crew stumble away to safety. Then the starboard petrol tank exploded. On reaching the aircraft Capt. Allen saw the pilot, who was injured and in a dazed condition, in the nose of the aircraft endeavouring to locate the observer. After removing the pilot Capt. Allen groped in the nose of the bomber, but was unable to find the observer. He continued his search around and over the port wing, which was well ablaze, in an endeavour to find the two remaining members of the crew. Fully aware of the danger from the possible explosion of the bombs, Capt. Allen remained in the vicinity, and finally, with an assistant, he removed the body of the gunner, which was found lying partly under the wing beside the blazing fuselage. Shortly afterwards three of the bombs exploded. Capt. Allen displayed great courage and devotion to duty.

F/O GEOFFREY HOWARD DHENIN, R.A.F.V.R., and Cpl. W. J. LUSH

One night in October, 1943, an aircraft, which had sustained damage during an attack against Hanover, crashed near an airfield. The aircraft disintegrated on impact and immediately burst into flames. The rear gunner was injured and trapped in his crushed turret, being pinned down by the remains of the tail unit and the rear of the fuselage. A high-explosive bomb was in the blazing wreckage some 10 yards away from the gunner. F/O Dhenin, the station medical officer, and Cpl. Lush, a gunner, hastened to the scene of the accident. Although fully aware that the heat might cause the bomb to detonate at any moment F/O Dhenin worked for over half an hour to relieve the injured airman's pain and, assisted by Cpl. Lush, endeavoured to release him. Their efforts to extricate the gunner were, however, unavailing. A mobile crane was brought to the scene and the mass of wreckage was lifted clear of the ground. Displaying complete disregard for his own safety, F/O Dhenin then crawled under the wreckage and released the trapped airman.

thereby enabling other helpers to drag him to safety. F/O Dhenin and Cpl. Lush showed fine courage and determination in circumstances of great danger.

The following have been mentioned in dispatches in recognition of gallant and distinguished services in the Middle East:

Brig. (Temp.) J. Walker, C.B.E., M.C.; Col. H. J. A. Longmore, late R.A.M.C., Brig. (acting) J. M. Macfie, O.B.E., M.C., Brig. (local) D. McAlpine; Col. (Temp.) D. Mackie, M.C., T.D., D. McVicker, M.C.; Col. R. H. Mollan, O.B.E., M.C., T. M. Pirrie, M.C., and W. Russell, M.C.; Col. (acting) C. Donald, C. E. Eccles, and R. Marnham; Majors (Temp. Lieut.-Cols.) I. Aird, C. Bainbridge, A. MacC. Campbell, A. M. Critchley, C. R. Croft, C. D. Evans, J. C. Hawksley, R. Johnston, P. J. Jory, D.S.O., J. M. Matheson, T. Parr, T. McK. Robb, J. R. Robertson, E. J. Selby, and W. L. Spencer-Cox, M.C.; Capt. (Temp. Majors) (acting Lieut.-Cols.) S. Brown (killed in action), and F. C. Mayo; Major (acting Lieut.-Col.) D. H. Young and Major W. H. Milligan; Capt. (Temp. Majors) J. H. L. Easton, T. J. Guinan, T. G. S. James, P. H. Jobson, R. L. Macpherson, R. J. Millbank, and P. D. Stewart; Capt. (acting Major) S. A. Jenkins; Capt. J. P. Baird, S. H. Campbell, W. G. Graham, A. P. Grant, J. N. T. Hutton, D. H. Jones, M. W. Lloyd-Owen, H. K. Lucas, D. D. Muir, C. F. Munro, R. L. Orchardson, W. D. B. Pettigrew, D. B. Ramsay, E. R. B. Reynolds, D. R. Sandison, M. A. Stammers, H. G. Skinner, F. M. Smith, M.C., G. A. Stephen, J. W. M. Sutherland, D. J. Waisterston, M.B.E., D. R. P. Wilkie, C. A. Young, and C. F. Young, M.C.; Lieut. (Temp. Capt.) T. Wright, R.A.M.C.; Capt. (Temp. Majors) C. H. Bliss, P. T. Joseph, and M. Sarwar; Capt. K. Partap Singh and S. C. P. Sinha; and Lieut. D. S. B. Stephens, I.M.S.; Subadar-Major K. S. Bedi, Bahadur, O.B.I., Subadar M. Singh, and Jemadar C. Hans, I.M.D.

### CASUALTIES IN THE MEDICAL SERVICES

Died.—Lieut.-Col. A. M. V. Hesterlow, I.M.S.

Wounded.—War Subs. Col. E. C. Beddows, M.C., Temp. Lieut.-Col. W. D. F. Lytle, War Subs. Capt. T. P. W. McCarthy, R.A.M.C.

### DEATHS IN THE SERVICES

By the death of Lieut.-Col. ROGER PARKER WILSON, C.I.E., I.M.S., on Dec. 12 at Southport the Indian Medical Service loses a distinguished and popular member. He was educated at University College, Liverpool, and St. Bartholomew's Hospital, London, passed the Conjoint finals in 1893, and took a good place at the entrance examination to the I.M.S. in 1896. Later he obtained the Cambridge D.P.H. in 1900 and the F.R.C.S.Eng. in 1912 while on leave. He served with the Indian Army until 1903, and was then appointed to the Bengal Civil Medical Service. After holding posts as civil surgeon in various districts he went to Calcutta to the important appointment of superintendent of the Campbell Medical School from 1913 to 1918, when he was promoted to be surgeon to Calcutta Medical College Hospital and successively professor of clinical surgery and professor of surgery in the Medical College. There he found scope for his abilities both professional and administrative, including examinerships, and as president of the Bengal State Medical Faculty and Council of Medical Registration. This led to his acting as Surgeon-General to the Government of Bengal in 1922 and 1925, and he was unfortunate in not obtaining a permanent administrative post before being precluded from further promotion by the age retiring rules. His various services were rewarded by the C.I.E. in 1925 and by his appointment as Honorary Surgeon to H.E. the Viceroy in 1920. He was joint author, with Rogers, of a paper on two cases of liver abscess treated by aspiration after early diagnosis by the blood changes—the first trial of the method now almost universally adopted. (*B.M.J.*, June 6, 1906.) Wilson was a most loyal colleague and was much liked by all his colleagues. In his young days he was a fine athlete and a good football player. Latterly he was much crippled by illness, but never lost his cheerfulness; he will be much missed by his many friends.

Lieut.-Col. JOHN LEWIS MACRAE, I.M.S.(ret.), died at Stornoway on Nov. 25, aged 75. He was educated at Blairlodge School and the University of Edinburgh, where he qualified M.B., C.M. in 1890. He entered the I.M.S. in 1891, and after military service in Burma and with the Peking Relief Expedition he became a district medical officer in the Madras Presidency and was stationed at Mercara as civil surgeon of Coorg for many years. He retired in 1921.

## Universities and Colleges

### UNIVERSITY OF GLASGOW

A graduation ceremony was held on Jan. 15, when the following medical degrees were conferred:

M.D.—K. S. Alstead, J. Black, A. A. L. Goodall, A. C. Pearman.  
Ph.D.—(in the Faculty of Medicine): Albert Sharman, M.D.  
M.B., Ch.B.—R. McL. Archibald, D. Beaton, Ellen S. Bell, G. M. Burns, R. Burns, C. Cameron-Mowat, K. D. Cochran, L. N. Cook, Margaret P. Delahan, Nialan C. Dick, Mary C. Douglas, A. M. S. Elfehah, Margaret J. W. Finlayson, J. Frazer, T. M. Gardner, Mary E. Hamilton, E. W. Hutcheson, P. McCulloch, D. A. MacDonald, W. G. McEwen, T. S. Macfarlane, M. M. Macgregor, J. Maclean, R. W. McKie, R. Meldrum, Katherine G. Miller, M. S. Miller, R. F. Miller, R. Mitchell, Alexandra Moffat, Lillian McA. Money, B. Moscow, Monica M. A. Murphy, W. L. Newbigging, Hetty B. Ockrim, W. G. Paterson, H. A. Rankin, F. E. Roche, L. M. K. M. Scrimgeour, J. Shapiro, Catherine G. Simpson, J. M. Sinclair, Margaret F. Smith, D. J. Stewart, E. McG. Stirling, Agnes C. Sutherland, R. Thomson, J. D. Wilson, Marjorie B. Wilson, J. D. Wimbis.

<sup>1</sup> With high commendation. <sup>2</sup> With commendation.

## Medical Notes in Parliament

### White Paper on Social Security

On Jan. 18 Mr. CHURCHILL, replying to Mr. Graham White said he hoped that the White Paper on Social Security would be ready about the end of February or early March, but he could not pledge himself to any particular date.

### Awards to R.A.M.C.

On Jan. 18 Sir JAMES GRIGG told Sir Harold Webbe that 204 awards and decorations other than for cases of conspicuous gallantry had been made to R.A.M.C. officers, and 22 to R.A.M.C. other ranks. In addition 499 officers and 381 other ranks had been mentioned in dispatches. No citations accompanied recommendations for mentions, and it was impossible to say how many of them were for cases other than gallantry.

### University Grants Committee

On Jan. 18 Sir JOHN ANDERSON informed Mr. Harvey that no change had been made in the terms of reference of the University Grants Committee, which were: "To inquire into the financial needs of university education in the United Kingdom, and to advise the Government as to the application of any grants that may be made by Parliament towards meeting them." It seemed to him that these terms of reference were wide enough to enable the committee to report on any problem on which the Government might need advice in connexion with the making of grants to universities. There had grown up between the committee and the universities an accepted custom of constant informal consultation on matters of university policy, and it was contemplated that this would be continued and developed. Mr. HARVEY asked if there was any possibility of the formation of a university council in the not distant future to make that consultation more effective, but Sir JOHN ANDERSON replied that he could not say anything about that.

### Registrar-General's Health Statistics

On Jan. 18 Major MARKHAM asked the Minister of Health whether he was aware that no detailed health statistics had been published for several years; and if he would give authority for the issue of up-to-date civil and medical tables or statistical reviews to supplement the summary reports of the Ministry of Health. Mr. WILLINK said that the Medical Section (Part I) of the Registrar-General's Statistical Review for 1940 was published last September and the Civil Section (Part II) of the 1939 Review last January. Corresponding volumes for subsequent years were being issued as soon as possible; but their production was conditioned by the very restricted printing facilities now available for this class of matter. During the present extreme shortage of paper the volumes could not be placed on public sale, but the statistics might be consulted at the Office of the Registrar-General, from whom a temporary loan of any volumes desired could be had by those having occasion to refer to them.

### Medical Recruitment in East Sussex

On Jan. 18 Rear-Admiral BEAMISH asked the Minister of Health if he was aware that the Central Medical War Committee was working a scheme with his Ministry which ignored the representations of the Local Medical War Committees and other committees concerned in East Sussex and, by designating too many local doctors for military service, was causing overwork and anxiety for those concerned with the health of the local population; and if he would adjust the situation. Mr. WILLINK replied that Admiral Beamish was no doubt referring to a plan which he had asked the Central Medical War Committee to put into operation on the recommendation of the Medical Personnel (Priority) Committee as one of the steps to obtain the number of doctors which the Government had decided to assign to the Forces. The plan applied to any area which had not satisfied the quota of doctors required of it—that was to say, which retained a higher proportion of general practitioners to population than that normally adopted for the purpose of calculating the quota. The Central Medical War Committee issued recruitment notices to doctors of military age up to the number required to make up the quota, but it was open to the Local Medical War Committee, as well as to the doctors themselves and any employing authorities, to make representations to the Central Committee against the recruitment. These representations were then considered fully by the Central Committee, at an oral hearing if so desired, before a final decision was reached.

## Medical News

Prof. B. A. McSwiney, Sc.D., M.B., will deliver the Oliver-Sharpey Lectures before the Royal College of Physicians of London on Thursdays, March 2 and 9, at 4 p.m., at the College, Pall Mall East. His subject is "Affluent Fibres of the Abdominal Viscera."

At the meeting of the Medical Society for the Study of Venereal Diseases to be held at 11, Chandos Street, Cavendish Square, W., to-day (Saturday, Jan. 29) at 2.30 p.m., a general discussion on "The Intensive Treatment of Early Syphilis" will be opened by Lieut.-Col. D. M. Pillsbury, senior consultant in dermatology, U.S. Army, in association with other American medical officers. At the meeting on Feb. 26 Col. J. E. Gordon of the U.S. Army Medical Corps will give an address on "The Prophylaxis of Venereal Disease."

The Friday evening discourses to be given at 5 o'clock at the Royal Institution, 21, Albemarle Street, W.1, include one on Brain Rhythms by Prof. E. D. Adrian, M.D., F.R.S., on Feb. 4; one on the Medical and Surgical Achievement of Soviet Russia in War by Mr. E. Rock Carling, F.R.C.S., on Feb. 25; and one on Habit and Evolution by Prof. D. M. S. Watson, D.Sc., F.R.S., on March 10. The following courses of lectures have been announced: Modern Developments in Dairy Science by Prof. H. D. Kay, D.Sc., on Feb. 1 and 8, at 5.15 p.m.; on Fungi and Modern Affairs by J. Ramsbottom, D.Sc., on Feb. 15, 22, and 29, at 5.15 p.m.; on the Mode of Action of Some Vitamins by Prof. A. R. Todd, D.Sc., F.R.S., on March 7 and 14, at 5.15 p.m.; on Chemical Factors in Nervous Effects by Sir Henry Dale, M.D., P.R.S., on March 21 and 28, at 5.15 p.m.; and on Food Fads and Food Fallacies by Sir Jack Drummond, D.Sc., on Feb. 24, March 2 and 9, at 2.30 p.m.

On Wednesday, Feb. 9, at 2.30 p.m., the Nutrition Panel of the Society of Chemical Industry will hold a meeting in the rooms of the Chemical Society, 56, Victoria Street, Westminster, London, S.W.1, when Mr. F. A. Robinson, M.Sc., F.I.C., will read a paper on the vitamin B<sub>6</sub> complex. The speaker will discuss not only the properties and distribution of these vitamins, but also their biological functions so far as they are understood.

On Feb. 10 at 7 p.m. at the House of the Pharmaceutical Society of Great Britain, 17, Bloomsbury Square, London, W.C.1, the Harrison Lectureship Medal will be presented to Mr. Arthur James Ewins, D.Sc., F.R.S. Following the presentation, Dr. Ewins will deliver the Harrison Memorial Lecture on "Progress and Problems of Chemotherapy." The development of chemotherapy in relation to pharmacy will be reviewed and attention drawn to some of the problems in the field of chemotherapy which still await solution. It is hoped that there will be a large attendance of members and friends. Refreshments will be served after the meeting.

Imperial Chemical (Pharmaceuticals) Ltd. ask us to print the following statement: It has recently been brought to our notice that toxic symptoms have occurred following anaesthesia in which trileine has been used with a closed circuit. Pending a full investigation of this matter, which is now being conducted, we would suggest that trileine should not be used with a closed circuit.

The Therapeutic Research Corporation of Great Britain Ltd. has elected the following officers for the year 1944: Chairman, Board of Directors, Mr. H. Jephcott (Glaxo Laboratories Ltd.); Deputy Chairman, Dr. F. H. Carr (British Drug Houses Ltd.); Chairman, Research Panel, Dr. A. J. Ewins (May and Baker Ltd.); Deputy Chairman, Mr. F. A. Robinson (Glaxo Laboratories, Ltd.). The Corporation has appointed Dr. Frank Hartley as secretary to take up duties early in 1944. The new offices of the Corporation are at General Buildings, 99, Aldwych, W.C.2.

Mr. Henry Berry, chairman of the Metropolitan Water Board, in a lecture on London's water supply problems before the Royal Society of Arts on Jan. 19, said that the use of larger quantities of chlorine for purification enabled the capital to escape any typhoid epidemic during the heavy air-raid period. At present all the Board's water supplies, whether from river or well, were chlorinated, but he would not be surprised if after the war the Board and other water authorities gave more consideration to the use of ozone as a purifying agent.

A meeting of the Court of Directors of the Society for Relief of Widows and Orphans of Medical Men was held on Jan. 5, with the president, Dr. R. A. Young, in the chair. A sum of £1,965 was voted to pay the half-yearly grants to the fifty-six widows in receipt of relief. Relief is granted only to the necessitous widows of deceased members, or their orphans if under the age of 16. Membership is open to any registered medical man who at the time of his election is residing within a twenty-mile radius of Charing Cross. Application forms for membership may be obtained from the secretary of the Society, 11, Chandos Street, Cavendish Square, W.1.

On Jan. 1 the Bristol Hospitals Fund (Inc.) and the Bristol Aeroplane Company Employees' Hospital Fund amalgamated and merged their funds and interests. As soon as legal formalities can be completed the Fund will be reconstituted as Bristol Hospitals Amalgamated Fund (Inc.), but meantime the Bristol Hospitals Fund (Inc.) will be legally responsible for the affairs of both the existing funds. Address for all communications: Royal London House, Queen Charlotte Street, Bristol, 1.

The latest Order on the control of liver, the Liver Extract (Regulation of Use) Order, 1944, which came into force on Jan. 8, permits the use of proteolysed extract as well as the injectable extract. The general effect of the Order is that liver extract, including desiccated liver, must not be used except in the treatment of pernicious or other megalocytic anaemias, and then only in the form of the injectable and proteolysed liver extract.

The Leverhulme Trustees invite applications for fellowships and grants in aid of research from British-born senior workers prevented by routine duties or pressure of other work from carrying out research. Forms may be had from the secretary, Dr. L. Haden Guest, M.P., Leverhulme Research Fellowships, Unilever House, Blackfriars, E.C.4. They must be returned by March 1.

The following resolution was adopted by the Council of the Malthusian League on Dec. 18, 1943: "Whereas there is an agitation for increasing the annual number of births in Great Britain; and whereas the Government has issued a White Paper (Cmd. 6358) which states that 700,000 births per annum, being the number annually born at the outbreak of the war, would maintain the present population for ever; and whereas no responsible person has advocated an increase of our present population: therefore the Malthusian League earnestly requests the Government to take no steps whatever which might lead to the increase of the annual number of births, especially among the poorer sections of the community, which are already multiplying very rapidly."

The British Homoeopathic Society has lately become incorporated into the Faculty of Homoeopathy, and an inauguration conference was held in London on Jan. 21 and 22, with the president, Sir John Weir, in the chair.

The issue of the *Indian Medical Gazette* for October, 1943, is a special tuberculosis number.

On Tuesday, Jan. 24, at the London Hospital, Whitechapel, in the presence of Sir John Mann, Capt. H. Brierley, and many distinguished physicians and surgeons, a tablet was unveiled to the memory of four radiographers—Ernest Harnack, Reginald Blackhall, Ernest Wilson, and Harold Suggars—who, to quote the inscription on the tablet, "devoted their lives to healing. Their work in the development of the science of x-rays cost them their health. This they gladly gave in the service of the London Hospital." Dr. J. H. Sequeira, in a memorial speech, briefly traced the history of x-ray development from the time of Roentgen. He then paid tribute to the four pioneers, whose "first thought was of their work and their last of themselves." Ernest Harnack joined the hospital staff as a clerk and later had the advantage of being trained by Dr. (now Viscount) Dawson. He started taking radiographs in 1896 with a primitive apparatus, and later he and Dr. Sequeira were able to use a more elaborate apparatus in the post-mortem room, where films were made to determine the value of the rays in diagnosing chest and abdominal diseases. Harnack was the first member of the hospital staff to suffer from x-ray dermatitis, and in 1909 he had to relinquish his work. Despite grave mutilation he lived until 1943, dying at the age of 72. Ernest Wilson, who joined the staff in 1899, contracted dermatitis of the fingers after only one year. He continued at work until 1904, but died of rapid cancer in the following year at the age of 39. Reginald Blackhall, who joined the staff when only 18, was particularly successful in stamping out ringworm among the children of the district. With Dr. Sequeira he carried out experiments with x-ray filters. In 1925 he succumbed to cancer at the age of 44. By the time Harold Suggars joined the staff in 1903 some of the risks of x-ray exposure were known, and he was the first worker to wear lead-lined gloves and body protection. Nevertheless he developed cancers on the body, face, and eyelid. He became almost totally blind from double cataract and died in 1943, showing amazingly cheerful patience and courage in his misfortune. "While we all admire courage," Dr. Sequeira said, "perhaps the most precious possession of all is that secret strength which shows the human spirit to be indestructible in the face of disaster."

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 8.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

\* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

## EPIDEMIOLOGICAL NOTES

## Discussion of Table

In *England and Wales* during the week the notifications of whooping-cough went up by 284, of diphtheria by 83, of dysentery by 76, and of cerebrospinal fever by 19, but there were 389 fewer cases of acute pneumonia, 238 of scarlet fever, and 31 of measles.

Influenza deaths in the great towns dropped to 255. (For the week ending Jan. 15 the figure is 197.) The largest returns were London 31, Sheffield 13, Liverpool 12.

Scarlet fever was down by 50 cases in Middlesex, by 42 in Lancashire, and by 40 in London; the only rises of note were in Staffordshire 27, and in Durham 22. The rise in diphtheria occurred mainly in the north, especially in Yorks West Riding which recorded 40 more cases than last week, Durham with 34 more, and Lancashire with an increase of 28. Whooping-cough notifications were up by 38 in Essex. Returns for measles were fairly steady, the only variation of note being in London, where the notifications have doubled in a fortnight.

Dysentery notifications were almost twice those of the preceding week. Two of the largest new outbreaks were in Sussex 27 (Bognor Regis U.D. 4 and Chichester R.D. 23) and the Port Health District of Liverpool 13. The other large centres of infection were London 22, Lancashire 22, and Surrey 15.

Notifications of cerebrospinal fever have risen from 53 to 92 during the past two weeks: a rise during the first quarter of the year has in recent years been a feature of this disease.

In *Scotland* whooping-cough notifications were up by 48, measles by 25, and diphtheria by 8, while scarlet fever was down by 36 cases, dysentery by 34, and acute primary pneumonia by 19. One-third of the cases of dysentery were notified in Edinburgh.

In *Eire* there was a general rise in the incidence of infectious diseases—diphtheria by 35, whooping-cough by 33, and scarlet fever by 11 cases. Of the 82 notifications of measles 52 were reported from Dublin C.B. and 17 from Roscommon, Castlereagh R.D.

## Quarterly Returns

*England and Wales.*—The birth rate during the third quarter of 1943 was 16.2 per 1,000 and was the highest rate for a September quarter since 1930. Infant mortality was 40 per 1,000 live births, this being the lowest quarterly rate ever recorded, and 4 below the average of the ten preceding third quarters. Stillbirths were 2.9% of the total births registered. Diarrhoea accounted for 998 deaths under 2 years of age, giving a rate of 5.9 per 1,000 live births, compared with 5.9, 5.9, 4.9, and 5.1 in the four preceding quarters. The general death rate was 9.4 per 1,000, compared with 9.3 for the third quarter of 1942, and an average of 10.0 for the September quarters of 1937-41. The natural increase—excess of births over deaths—was 70,839, and the increases during the September quarters of 1940-2 were 37,359, 46,285, and 71,000 respectively. The marriage rate, 15.6 per 1,000, is the lowest rate for a third quarter since 1917: 162,908 persons married in the quarter, 28,518 fewer than in the third quarter of 1942, and 87,947 below the average of the five September quarters before 1942.

*Northern Ireland.*—During the September quarter the births were equivalent to a rate of 23.8 per 1,000, being 2.7 above the average for the third quarters of 1938-42. Infant mortality was 76 per 1,000 registered births, and was 12 above the average of corresponding quarters of the five preceding years. The general death rate was 11.2 per 1,000, and was 0.3 below the average of September quarters for the preceding five years. The death rate from the principal infectious diseases was 0.75 per 1,000, compared with the five-year average of 0.57. This rise was due to diarrhoea and enteritis under 2 years; 167 deaths were attributed to this cause, against an average of 106. Deaths from pulmonary tuberculosis were 188, and 67 from other forms of tuberculosis; the averages of the five preceding third quarters were 211 and 71.

## Week Ending January 15

The returns of the notifications of infectious diseases in *England and Wales* during the week included: scarlet fever 1,747, whooping-cough 2,023, diphtheria 673, measles 559, acute pneumonia 1,294, cerebrospinal fever 64, dysentery 175, paratyphoid 4, typhoid 1. Influenza deaths in the large towns numbered 197.

F. S. Cheever, B. B. Breese, and H. C. Upham (*Ann. intern. Med.*, 1943, 19, 602) found that sulphadiazine was effective in clearing the nasopharynx of meningococci in 161 meningococcus carriers receiving 8 g. of the drug over a period of 72 hours. No untoward results of the drug were noted.

## Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111

TELEGRAPHIC ADDRESSES—EDITOR, *Attolores Westcent, London* SECRETARY, *Medivacca Westcent, London* ADVERTISEMENTS, *Articulate Westcent, London*

B.M.A. SCOTTISH OFFICE: 7, Drumthugh Gardens, Edinburgh.

### ANY QUESTIONS?

#### Which Sulphonamide?

*Q.—In view of the introduction of new sulphonamides, I should be glad to know which is now considered to be preferable for the treatment of pneumonia due (a) in the pneumococcus, and (b) to other organisms, such as the staphylococcus, streptococcus, Friedländer's bacillus, etc.*

*A.—*No dogmatic answer to this question is justified. There is neither experimental nor adequate clinical evidence on which to assess the relative merits of the newer sulphonamide compounds, particularly for the less common forms of pneumonia. All are believed to act in the same way, and choice may depend not so much on specificity of effect on a particular micro-organism as on some other and perhaps subsidiary property.

With the exception of sulphathiazole, all compounds in common use have a satisfactory action on the pneumococcus. Sulphapyridine, the first to achieve this, and still the most widely used, has a drawback in its strong tendency to produce nausea and vomiting. This is overcome in sulphadiazine, which achieves much the same therapeutic result with far less discomfort to the patient. Sulphamezathine closely resembles sulphadiazine, and has the further advantage of greater solubility, both of the drug itself and of its acetyl compound; absorption is thus rather more rapid and the deposition of crystals in the urinary tract, causing haematuria or ureteric obstruction, is most unlikely to occur with this drug. It is also rather more slowly excreted, and less frequent dosage will therefore serve.

There is good evidence of the efficacy of sulphapyridine in infections due to *H. influenzae*, of sulphathiazole for staphylococcal infections, and of sulphadiazine for those due to Friedländer's bacillus. This is not to say that other new compounds will not serve equally well. Haemolytic streptococcal infections respond to any of the sulphonamides, including sulphathiazole, but in pneumonia the choice should perhaps fall on one with the least possible tendency to cause nausea or cyanosis, such as sulphadiazine or sulphamezathine.

#### Menopausal Flushes

*Q.—I should be grateful for some information on the treatment of the hot flushes and sweatings incidental to the menopausal changes. In the case I have in mind the attacks occur at night—often as many as six—and are very distressing.*

*A.—*The specific treatment is by means of oestrogens. A previous answer on oestrogen therapy for menopausal symptoms (*Journal*, Aug. 7, 1943, p. 190) was, by reason of its brevity, open to some misunderstanding, and attracted some valid criticism from Dr. P. M. F. Bishop in a letter published in the *Journal* on Aug. 21, 1943, p. 244. The original answer and this letter should be consulted. Whatever differences of opinion there may be in other respects, all are agreed that the patient should be given the smallest dose of oestrogen which will relieve symptoms, the actual dose employed being a matter of trial in individual cases. Natural or synthetic oestrogens may be employed, the latter being relatively more powerful in their effects, especially when administered orally. In this particular case only a very small dose should be required, and oestrone or oestrone benzoate 0.1 mg. or 0.2 mg. t.d.s. by mouth should be tried in the first place. If this is inadequate it can be cautiously increased, and, if need be, supplemented by a weekly intramuscular injection of 5 mg. oestradiol benzoate. Alternatively, and again if a large dose proves necessary, a synthetic oestrogen such as stilboestrol 0.5 mg. once or twice daily by mouth can be employed. The object should be to ameliorate symptoms rather than relieve them completely. Having arrived at the smallest dose which achieves this object, maintain that dose for two to three weeks, and then gradually reduce over the course of several weeks. By the end of three months it should be possible to discontinue

treatment completely. An essential feature of the treatment is the regular and gradual reduction in dosage—thereby allowing the body to readjust itself to the altered endocrine balance. Symptoms will recur if treatment is stopped suddenly. If for any reason oestrogen therapy is contraindicated then a small dose of thyroid, or a large dose of calcium, or vitamin E, is worthy of trial.

#### "Booster" Doses in Typhus Immunization

*Q.—An antigen prepared from typhus rickettsia grown in the yolk sac of developing chicks is being extensively used for immunization purposes. For the initial inoculation the three graduated doses are given at weekly intervals. Thereafter three-monthly "booster" doses are recommended. Is there in fact any weight of scientific data to back the recommendation that reinoculation should be performed at such very short intervals? I know of no other active immunization procedure which demands four "booster" doses per annum to maintain immunity.*

*A.—*Immunization against louse-borne typhus is still in the experimental stage. Rickettsial vaccines are now employed on a large scale for the first time, and so far little is known about their prophylactic value in the field. Reports from German sources indicate that inoculation with the available vaccines, including those made from infected yolk sacs, does not prevent subsequent infection, but greatly reduces the severity of the disease. It is not known for how long this state of relative immunity lasts following the three doses that are given in the course of the initial inoculation. The laboratories issuing yolk-sac vaccines recommend reinoculation at various intervals—for instance, every four to six months, or every three to nine months. In view of the high fatality rate recently observed in some localities in cases of louse-borne typhus it seems to be a wise decision to adopt the short intervals for reinoculations so long as there is serious danger of infection. It would not be safe to rely on experiences with other immunization procedures. Rickettsiae occupy a position quite separate from the bacteria and the filterable viruses, and the conditions governing immunity to rickettsial infections may differ in many respects from those obtaining in the other groups of micro-organisms.

#### The "Stammering Bladder"

*Q.—In his book "Sympathetic Nervous System in Disease" Sir Walter Langdon-Brown refers to the "stammering bladder." I should be glad to know just what the physical explanation of this condition is.*

*A.—*"Stammering" of the bladder is a neuromuscular incoordination, due to a disturbance of the balance between the sympathetic and parasympathetic innervation to that organ. This results in alternations of precipitate micturition with mild stranguary. It is therefore allied to other forms of neuromuscular incoordination.

#### Retarded Speech

*Q.—A boy aged 2½, healthy in every respect, can only utter animal sounds. He cannot speak any words, not even "mo" or "ta," although he appears to understand everything that is said to him. What treatment and advice should be given? The family history is quite good. Three other boys, aged 11, 7, and 5, in addition to the mother and father, are all in perfect health. These boys began to talk soon after they passed their first birthdays.*

*A.—*In all probability this child is either deaf or mentally defective, or has some type of congenital auditory aphasia. Despite the statement that he appears to understand everything, his hearing should be most carefully tested. He may be lip-reading. As regards his mentality more information is needed. Has he passed all his milestones at the proper time? When did he hold up his head?—sit up?—walk? Has he control of his bladder and rectum? If his hearing is normal and there is no evidence of mental retardation, then he may have some form of aphasia for which special coaching by a speech therapist is desirable. But it might be worth while waiting another six months or so, as there are occasional late talkers who suddenly begin to talk normally as late as 3 years or more.

#### Thyroid Treatment of Cretinism

*Q.—I have a patient, a cretin, aged 22. For two years she had thyroid treatment—between ages 2 and 4—and the mother then stopped the treatment because it made the child too excited. Judging from photographs I should say there had been definite improvement during the period of treatment. Of course she is now a stupid imbecile. Is there any use in trying thyroid now, and if so, what dose do you recommend?*

*A.—*With cretins who have not received treatment continuously, and who show signs of imbecility, the prognosis is bad, with or without the institution of hormone therapy. The administration of thyroid gland might convert a somewhat docile lethargic imbecile into a very active aggressive and awkward person, with resulting difficulties of management. Nevertheless, I do not consider it

justifiable to withhold thyroid treatment, as beneficial results are not impossible. Should the outcome be unsatisfactory it is always possible to cease thyroid therapy, and after some weeks the condition will probably return to the same state as before. Incidentally, even cretins who have received continuous and adequate therapy from birth or infancy may, after many years, show mental deterioration which is not amenable to hormone therapy. As regards the dosage of thyroid, in this and other cases it is determined by the general response and the pulse rate, but more accurately by the estimation of the basal metabolic rate.

#### Epididymitis

**Q.**—A male patient aged 73, active and working, consulted me five years ago for an acute epididymitis and has been under treatment ever since. Bacteriological examination revealed a "free growth of *B. coli*," and x rays showed the presence of two calculi in his prostate. No pyelitis. He passes urine freely, which contains threads. He was treated with mandelic acid and sulphonamides, with slight amelioration only, until he was put on hexamine, small doses of which make him fairly comfortable. He has now developed an acute epididymitis (second attack). He has arteriosclerosis, feels the cold very much, has persistent backache (relieved by massage), polyuria, and a painful tingling of the soles of his feet—no chilblains. Urine has always been alkaline; prostate not unduly enlarged. A recent report says urine is alkaline, specific gravity 1010, faint cloud of albumin, no sugar, small amount of pus, a small number of red blood cells, moderate deposit of amorphous phosphates, moderate numbers of triple phosphate crystals, a few squamous epithelial cells, large numbers of bacteria, and free growth of *B. coli*.

**A.**—The most urgent trouble at the present moment would appear to be the epididymitis, and even though sulphonamides did not appear of benefit previously, it would be worth while putting him on sulphathiazole now. Recurrent attacks of epididymitis are frequently associated with a fibrous prostate containing calculi, and in one or two cases I have known they were so frequent that I divided the vas in order to cut the path along which the infection travelled. As there appears to be no difficulty of micturition or retention, it is not necessary to operate on the prostate. It is not stated whether the pH was estimated when the patient was previously on mandelic acid, and as the urine is persistently alkaline supplementary doses of ammonium chloride would probably be necessary. Mandelic acid treatment is often reported to have failed when its failure is due to a pH of 5.5 not having been attained.

#### Halitosis

**Q.**—What suggestions have you for the treatment of halitosis in a woman of 40? Tonsils have been removed, teeth and gums appear quite normal, and she has no indigestion or constipation.

**A.**—Fetor oris is due to contamination of the expired air, and, if there is no disease of the nose, mouth, pharynx, or lungs, it is usually caused by food particles which are retained in the mouth and undergo putrefaction. Only occasionally is it the result of volatile chemicals, such as alcohol and acetone, which are excreted into the alveolar air from the circulating blood. It is probably never derived from the stomach except as a momentary effect during belching. The condition should be treated by careful brushing of the teeth and the use of mouth washes after every meal. If there is much furring of the tongue this should be cleaned with a soft toothbrush which should be applied gently and as far back as possible. The best chemical cleaners to use are hypochlorites such as Dakin's solution or chloramine compounds. Between meals the patient may be allowed to suck tablets containing 5 gr. potassium chlorate, but she should be warned of the danger of carrying these carelessly in the pockets as there is a risk of fire from contact with matches.

#### Decaying Teeth in Children

**Q.**—Children, ages ranging from 2 to 8, are often seen with one or more teeth in varying states of discoloration and decay. What principles should guide a doctor in advising filling or extracting in such cases?

**A.**—Unless the doctor has the facilities and necessary instruments for excavating the decay from the cavity in the tooth, so as to determine the vitality or otherwise of the pulp, it is indeed difficult for him to advise on this matter, and the decision had better be left to the dental surgeon. If there is no exposure of the pulp then every effort should be made to conserve the tooth in question, but a parent is not likely to approach the doctor unless her child has toothache or some swelling of the face. Bad toothache means that the pulp is already infected, and even with careful dressing and filling the pulp may die and an abscess develop. A dead tooth in a child of this age should always be extracted, as it is sure to become a cause of pain or ill-health. Remember to look out for those small localized abscesses or "gumboils," which may burst and leave behind a sinus without the child complaining. The treatment of early decay will save many hours of pain and unhappiness.

#### "Luis," "Louis," "Lewis," or "Ludwig"?

**Q.**—The angle between the manubrium and the gladiolus is sometimes termed the angle of Luis (?), Louis (?), or Lewis (?). Which is the correct spelling, and who was Luis, Louis, or Lewis?

**A.**—The correct spelling is "Louis." Antoine Louis lived from 1723 to 1792. He gave lectures on anatomy in Paris and led the way in the application of medical knowledge to legal problems, taking a hand in various famous cases (Garrison). The German form of the phrase is "Louis'scher Winkel," but the name Louis has sometimes been translated into German as "Ludwig" in this country and elsewhere. Braune stated in 1889 (*Arch. Anat. Entw.*) that he had examined Louis's writings in vain for any reference to this angle, and that the first reference of association with Louis's name occurred in Conrad's book, *Position and Form of Thoracic Organs*, published (in German) at Giessen in 1848. It is probable, however, that the first instance of association would occur not in the author's own writings but in those of someone following shortly afterwards. There was a German anatomist named Ludwig living much earlier (1625-80), but no evidence can be found that his name was ever attached to the angle. The following early works make no reference to Ludwig in this connexion: Cowper (1698), Albinus, *Tables of the Skeleton* (1749), and Cheselden's *Osteographia*. It is probable that Louis's name is correctly associated with the angle.

#### LETTERS, NOTES, ETC.

##### Food-poisoning in S. Devon

**Dr. J. C. CRICKSHANK**, in reference to the answer to the question on food-poisoning in South Devon in the *Journal* of Jan. 1 (p. 30), points out that the service of the Devon County Laboratory, now supported by its association with the E.P.H.L.S., provides for all practitioners in the county full facilities for laboratory and field investigation of such outbreaks as the one described. It appears that all practitioners in the county should have received the full and informative E.P.H.L.S. Memorandum, No. 2, entitled "The Laboratory Diagnosis of Enteric Fever, Dysentery, and Bacterial Food Poisoning."

##### Extra Milk for Patients with Influenza

**Dr. GUY NEELY** writes: During the past few weeks many victims of influenza have needed extra milk. To expect them to rise from their beds—for there is seldom anyone to look after them—still less to travel a mile and a half, wait in a queue at the food office, and take the permit to the food depot is perhaps a little unreasonable even in this bureaucratic age. Why cannot the milk form be given direct to the roundsman, or is this too easy?

##### Post-herpetic Neuralgia

**Dr. E. MILLINGTON (Hove)** writes: The answer given to the question about treatment of post-herpetic neuralgia (Jan. 1, p. 31) makes no mention of any form of radiotherapy or physiotherapy, and paints a gloomy picture generally. In many cases complete relief from this pain may be obtained by x-ray treatment, even with a history of many years, and other cases are helped by electrotherapy and short-wave treatment. X-ray therapy will often alleviate otherwise intractable pain in cases of trigeminal neuralgia, brachial neuritis, and other forms of neuritis, although there is no way of selecting suitable cases beforehand, and some cases will show no response, unfortunately.

##### Wanted—Cade's "Treatment of Malignant Diseases"

The Anglo-Soviet Medical Council has received a special request from the Soviet Union for a copy of Stanford Cade's *Treatment of Malignant Diseases*. Most copies of the book have been destroyed by enemy action. The Council would therefore be grateful if any reader would be willing to sell his copy. Anyone wishing to do this should communicate with Dr. E. Bunbury, Fountain Hospital, London, S.W.17.

##### Corrigenda

**Dr. J. B. DAVEY** wishes to make the following corrections in his letter headed "Colonial Research" printed on Jan. 15 (p. 97): The words "medical work" in line 7 should be preceded by the word "routine"; the name "Ranson" in line 8 should of course read "Manson" (Sir Patrick); and the word "individual" in line 20 should read "individualist."

In line 19 of the first paragraph of the leader on the epidemiology of scarlet fever (Jan. 22, p. 118) the words "over a month" should read "once a month," and in line 14 of the third paragraph the words "these are" should read "there are."

## SOME PRINCIPLES OF REFORM IN MEDICAL EDUCATION

BY

F. M. R. WALSHE, M.D., D.Sc., F.R.C.P.

The recasting of medical education, having been a topic of recurrent discussion for many years, begins to show signs of becoming a subject of action, and the two reports recently issued by committees of the Royal College of Physicians on social and on psychological medicine lay down lines of reform that seem expedient to some of our number. It is probably reasonable to assume that the two reports are but the heralds of comparable recommendations in respect of other branches of medicine, and there are signs that the specialists will shortly be on the march at the head of thousands of words, determined to bend the medical student to their will.

### The Need for Revision

Few would deny that the methods and content of our present teaching call urgently for revision, but if we were to ask at large, "What are the important defects in the educational diet we provide for the medical student?" we should probably get as many and as diverse answers as there are special aspects of medicine, though we dare not be so sanguine as to anticipate that many of these answers would be the fruit of general ideas on the subject, or that they would dive beneath the surface of the obvious symptoms in search of fundamental faults. We should probably be assured on almost all hands that the student must know more about most of the special branches, and must acquire familiarity with more, and more complex, techniques.

That this is no wild surmise is plainly exemplified in the report on psychological medicine already referred to. This suggests a fully detailed syllabus comprised as follows:

#### *During the Preclinical Years*

12 to 20 lectures on normal psychology.  
Visits to schools, courts, and factories.

#### *During the Clinical Years*

6 introductory lectures on clinical psychology and psychiatry.  
53 further lectures and demonstrations on specified aspects of the subject.  
Seminars and discussion groups covering the whole field.  
Three months' clinical clerking to an in- and out-patient psychiatric department of the hospital.  
A short term of undergraduate residence in a mental hospital, or, alternatively, a clinical clerkship in a mental observation ward.  
A series of domiciliary visits with a psychiatric social worker.  
Finally, a special qualifying examination comprising written, clinical, and oral parts.

The avowed object of this course is "to produce a sound general practitioner and not a specialist in psychological medicine"; but it is admitted that "the proposed syllabus makes demands for a greater share of the time of the medical student."

On the whole, the report on social and preventive medicine is less concerned to formulate an ambitious syllabus, and more interested in a reorientation of some of the teaching in already accepted items of medical training. It is content with a modest allowance of 18 to 20 hours in lectures, and does not demand the 70 or more hours deemed essential by the psychiatrists

for their subject. Yet the report states, "Even so, the curriculum proposed will make further demands on the time of the medical student which can only be met by modification of some other part of the curriculum." It adds later, "The course in preventive and social medicine, as in the clinical subjects, *should become a curriculum.*"

Here we see both reports demanding for their special branches of medicine more time and labour from the medical student, and the casual recognition by one only of them that this is to be made possible by the pruning of "some other part" of the curriculum. To anyone who can read the omens it is clear which way the wind of reform is going to blow. More and more is to be expected of the medical student; no one gives serious thought to assessing the burden he can reasonably be expected to bear, but each branch of medicine vaguely cherishes the fond hope that some other branch will be ready to make the sacrifices essential to the fulfilment of its sectional ambitions, and to the adoption of its private curriculum. Yet if sectional interests are to be given a free hand, and if we concentrate excessively upon partial aspects of medical education, we shall never achieve a rational educational plan, and the student of the future may well find himself crushed beneath an intolerable burden of uncoordinated syllabuses, private curricula, and easy counsels of perfection.

However, it must be said that quite another view of these reports has been expressed (*vide* Lord Moran, *Times*, Nov. 3, 1943), to the effect that they do not propose "to add a new set of facts that the student must try to remember. They are merely intended to foster a habit of mind, a way of looking at things." No one who has studied these reports and done justice to their diverse merits can possibly accept this gloss, for both of them explicitly propose to lay fresh burdens of factual knowledge upon the student—one of them to a quite extravagant extent. Therefore, if the point of view embodied in these proposals prevails, a medical course will become a long and arduous sentence, and one to which few prudent parents will wish to submit their sons or daughters, and which still fewer schoolmasters than at present will care to recommend to their brighter pupils.

It is hard to believe that this is the way of wisdom or of sound reform. It seems to confuse instruction with education, shows little psychological insight into the methods and purposes of education in the true sense, and does not pause to ask the important question of what, in general terms, we wish the finished product of a medical training to be capable. The formulating of a final aim is a necessary preliminary to any scheme of educational reform. Only when we have decided upon this aim can we proceed to draw up the plans necessary to its attainment, having in view the time and the resources available.

If we have in fact reached a wide agreement as to the necessity for change it is because we have been forced to admit defects in the methods and content of our present teaching. Yet we have to bear in mind that as these defects first come to notice they may be but symptoms of more deeply seated disorders inherent in our present methods. If this is so, we shall do no good by patching up and adding to an unsound structure; we must rebuild from the foundations up. To do this we must undertake a thorough and critical analysis of

such defects as have come to notice, for unless we do so we shall find ourselves attempting treatment without adequate diagnosis: a type of enterprise not wholly unfamiliar to us in clinical medicine.

### A Criticism of Achievement and Outlook

A critical survey of the house of medicine to-day shows that it is far indeed from being in order. Not the greatest and most justified enthusiasm for recent advances in knowledge, or for the alleviations of human suffering we have seen in our time, can blind us to the existence of many grave deficiencies in our achievements and outlook. We talk very facetiously about the science and art of medicine, but it may be argued that the "science of medicine" is still a somewhat shadowy conception. From time to time this has been pointed out to us by one or other of those rare philosophers who have found themselves in our ranks, but the thought has been too unwelcome for us to listen to those who remind us. Allbutt, Mereiter, and more recently Crookshank have all drawn attention to the unsatisfactory state of our science and its neglect of a rational use of language. Thus, says Crookshank, "although the Art of Medicine has been greatly advanced, in many respects, during the last century: although the Practitioners of that Art do freely draw upon the vast storehouse of facts called scientific, to the great benefit of suffering humanity: and although all medical men have some acquaintance with certain sciences of which the province is in part continuous with that of the Art of Medicine, there is to-day no longer any Science of Medicine in the formal sense. It is true that observation and thought have led medical men to form generalizations which have obtained acceptance; but there is no longer any organized or systematized *corpus*, or formulated theory, which can be held to constitute the Science of Medicine, and (in a now obsolete terminology) to form an integral part of Natural Philosophy. . . . Her Professors and Doctors decline to define fundamentals or to state first principles, and they refuse to consider, in express terms, the relations between Things, Thoughts, and Words involved in their communications to others."\*

Again, "though we accumulate what we call 'facts' or records of facts without number, in no current textbook is any attempt made to define what is meant by 'a disease.' . . . In a word, no attempt is made to distinguish between what we observe in persons who are ill, on the one hand, and the general notions we form in respect of like illnesses in different persons. . . . in hospital jargon, 'diseases' are 'morbid entities,' and medical students fondly believe that these 'entities' somehow exist in *rebus Naturae* and were discovered by their teachers much as was America by Columbus."

### Precision in Language and Thinking

This fallacy of "misplaced concreteness" infests medical writing and leads even in the most distinguished hands to shocking confusion of thought. Two examples of this are cited in the paper from which the foregoing excerpts are taken—namely, the statement that "lethargic encephalitis is altering its biological properties" and that "a disease is only revealed by the symptoms it produces." Yet the two terms "lethargic encephalitis" and "a disease" are no more than general notions or abstractions, and abstractions have no biological properties and can "produce" nothing. It is a human weakness to hypostatize abstractions—often a pardonable and harmless weakness; but that at the fountain-head of medical thought and teaching we should find this grotesque confusion of thought and language, this failure to distinguish between thoughts, words, and things, is an indictment of the state of our science.

It is surely impossible that we should forge generalizations and propound first principles until we have given precision to our language and thinking. Sir Almroth Wright has recently commented pungently upon the poverty of our terminology; but even the most adequate terminology needs to be used in a framework of rational language if it is not to add to our confusion.

\* *The Importance of a Theory of Signs and a Critique of Language in the Study of Medicine*, by F. G. Crookshank; being Supplement II in *The Meaning of Meaning*, by C. K. Ogden and I. A. Richards. Kegan Paul and Co., 1936.

At this stage in my thesis it is certain that I shall beg to meet with objections. That familiar phenomenon of the successful and euphoric individual who flatters himself that he is a hard-headed and practical man will make his usual and instinctive protest against the use of the intellect by saying that all this talk of language is but a splitting of hairs. Yet even a brief consideration will show that our slovenliness in thinking and in use of language exerts a profound effect upon our teaching. We are teaching clinical medicine merely empirically in terms of "diseases"—save in the case of neurology and cardiology, in which the tendency to think of symptoms and signs in terms of disordered function in normal structures has long been dominant—and not in terms of the range of bodily reactions to a variety of noxae. The student is led to think of illness wholly in terms of largely conventional groupings which are constantly changing, and to believe that "a disease" is a concrete agent that "does things" and produces symptoms. So taught, he is ill equipped to deal with new and unfamiliar reactions or sets of reactions, and cannot handle new and strange experiences as he should. He has to remember a great deal, but may understand very little of the processes and manifestations of illness. No general principles have been imparted to him. Recurrent changes in terminology and methods add to the difficulties of his task. It has to be admitted that as yet we understand very few diseases fully, and even many common manifestations of illness have so far escaped explanation. There is a rapidly growing mass of facts that yet await interpretation and have not yet been brought under adequate generalizations. This is a time in the history of medicine when new facts are being added to our stock faster than we can—or at least than we desire—to sort them out or build them into an ordered fabric of knowledge, and much therefore must remain as necessary matter for memorizing.

Added to the accession of new facts, to the unending flux of opinion and terminology, and to the constant arrival of new methods, is a spate of books and journals—good, bad, and indifferent, all competing for the student's attention—carrying on its surface a flotsam of seductive advertising literature on treatment that influences thought and practice far more than is good for medicine. It is in these trying circumstances that the student has to learn, and the doctor to practise medicine. Of the coherence and more fully reasoned arguments, and of the precise terminology of the ancillary sciences of anatomy and physiology, we see ever less trace in clinical teaching and writing as the mass of unrelated facts and hypotheses accumulates round us.

Nothing is more clear than that we lack both an adequate language—and the rational use thereof—and a body of first principles in medicine, and also the will to provide ourselves with a body of theory based upon these necessities of a science of medicine.

### General Principles of Medicine

The plea is therefore made that some attention shall be given to the theoretical aspect of medicine, and to its formulation and teaching, in any proposed reform of medical education. We who are teachers cannot but confess that too few of us have set ourselves to this urgent task; to synthesizing the information at our disposal, and to the elucidation of fact by clear generalizations. We have been too willing to follow the beaten paths of routine clinical teaching, or, when engaged in research, too eager to add to the bulk of raw information to be willing to pause for thought and to take up the difficult task of developing a general theory of medicine and of eliciting general principles. In short, we have found action—of one kind or another—easier than thought, and it is greatly to be feared that it is in this uninspired frame of mind that we are contemplating a reform of the curriculum.

It is the fundamental defect of our teaching that we have not given the student a firm grasp of general principles, we have not taught him to weigh evidence, to discriminate or to think logically, and we have too often failed to imbue him with that keen desire for understanding that is the essence of true education. We have been content to preoccupy him with feats of memorizing and with the acquisition of an increasing number of techniques.

If, at first sight, it seems unfair to indict the finished products of our teaching with being less than adequately endowed with critical faculty and scientific thought and method, we have only to look round on the medical scene to discover very numerous examples of these basic faults.

They are to be seen in every aspect of medicine and in every category of doctor, both teachers and taught. One disquieting example is the prevalence of unsubstantiated general notions about ill-health. Thus there are still far too many for whom those ill-defined conceptions, "focal sepsis" and "auto-intoxication," provide a sort of "reach-me-down" explanation of almost every variety of chronic illness. Holocausts of teeth and tonsils have been offered up on the altar of this notion, and there can be few maladies—psychological or somatic—which have not been hopefully, if irrationally, treated by these crude procedures, or by the indiscriminating devastation of air sinuses.

Not less indicative of unsound standards of thought is the tendency to assume that in a given case any improvement that follows the administration of a particular remedy must be directly due to its pharmacological action, and a succession of subsequent disappointments to secure benefit often fails to correct the first and hasty impression or to abate our wishful thinking. Although we are all aware of the *post ergo propter* fallacy, it has all too little influence upon our judgments.

The indiscriminate use of almost every newly discovered product of chemical ingenuity is another disturbing feature of modern practice. Few middle-aged women in ill-health can now hope to escape a course of stilboestrol; the sulphonamide drugs are not always used with conspicuous judgment; and our wholesale employment of vitamin preparations might lead the naive observer to suppose that we have found in them a panacea for a wide range of human ills. Doubtless in course of time a sound balance of opinion is reached in respect of all such remedies, but only after much wasteful use and to the accompaniment of fresh uncritical enthusiasms for yet newer remedies. These are matters we dare not continue to tolerate with equanimity.

A striking instance of the ephemeral fashion in theory and practice is provided by psychological medicine in our day. For at least a quarter of a century, and in a literature of unexampled volume, we have been presented with elaborate, and not always harmonious, hypotheses of the psychological genesis and treatment of psychological disorders, major and minor. We have been encouraged to regard the mind as a sort of *chimaera in vacuo bombinans*, and the personality as an entity standing in no relevant relationship to the brain. Yet within the past three or four years we have been seeing an increasingly rapid flight from psychotherapy in favour of the treatment of psychological disorders by physical assaults upon the brain, in the form of chemically and electrically induced convulsions and of mutilations of the frontal lobes. Here we observe, not a scientifically controlled and recorded experimental approach to a new theory and treatment, but a widespread and too often wholly uncritical and inadequately documented employment of drastic procedures the perils and final fruits of which cannot yet be seen. Psychotherapy, meanwhile, still remains the logical corollary to hypotheses of causation that have nowhere been explicitly abandoned; but none of those who, while "on with the new," are not yet "off with the old" seem to have noticed the antinomy inherent in this therapeutic right-about-turn.

It can hardly be maintained that the prevalence in medical thought and practice of what Tristram Sbandy called "hobby-horshical" tendencies, and of the other defects exemplified, can justly be attributed to a mere dearth of information imparted to the doctor during his period of training. They surely arise from those underlying faults that have already been called fundamental, and they cannot possibly be remedied by still further increasing the amount and range of factual knowledge we expect of the student.

#### Training in the Theory of Medicine

We have been too preoccupied with the vocational and technological aspects of training, and too little interested in the theoretical basis of medicine. We have taught medicine too exclusively as a practical art, and, largely unnoticed by us,

medicine has been passing from the stage of simple observation and of empiricism to one in which theory must play an ever larger part. In our hands, it is true, a great deal of medicine has not reached a stage in which broad generalizations are practicable, and much memorizing of facts remains a necessary task for the student. Nevertheless, we might make this easier for him by emphasizing general principles even in the purely vocational side of his training. By this we refer to clinical observation and the methods of diagnosis and treatment, and to the acquisition of a sound basic factual knowledge of disease. Yet this is clearly not the whole of an educational process, and does not by itself give the student sound habits of training, does not teach him how knowledge has been and is being gained, nor impart the ability to recognize sound sources of information and to reject ill-founded speculation and the wishful thinking that plays so large a part in our therapeutic assessments.

If these intellectual aims are to be realized we shall need teachers with a special interest in disease as a whole rather than in individual patients, who will teach on clinical material primarily to display and exemplify general processes of disease. They will have to concentrate upon the making of generalizations and the weaving into a pattern of the many and at present largely unrelated strands that make up the general body of medical knowledge. It becomes increasingly difficult for the independent clinical teacher engaged in private practice to undertake this task as it deserves and requires, and its pursuit may well be the main function of those whole-time academic teachers who are already established in some of our medical schools, and whose numbers will surely have to be increased in future. It would be naive indeed to suppose that a man's capacity for generalization and interpretation can ever depend primarily upon the sources from which he derives his living. Practising physicians who are clinical teachers may in the future, as they have in the past, give us some of our most penetrating generalizations. What is suggested is that we shall choose our professors of medicine from those who have given some indication of their capacity for and interest in general ideas, and that in virtue of their status and freedom from the harassing conditions of private practice they will be free to devote part of their talents undisturbed to the building up of a theory of medicine. This essential task in the building of ordered knowledge will have in future to receive its due share of academic recognition if men are to be encouraged to undertake it; for the transmuting of information into ordered knowledge is a task not less difficult, or less essential, than the acquisition of new facts: a consideration to which in this generation we have been strangely blind, as the present chaos in medical thought sufficiently witnesses.

#### Pruning of the Curriculum

In addition to this rebuilding of the very foundations of medical education, there can be no doubt that an urgent need is a quite ruthless pruning of the range and amount of factual knowledge we expect of the student. These must be cut down. We cannot rationally expect that the newly qualified doctor shall be the complete obstetrician, paediatrician, psychologist, orthopaedist, and expert on hygiene and social medicine.

There will doubtless be a chorus of protest that no one does expect this; yet if we assess the separate opinions of specialists upon what they want for their own branches this is precisely, by implication, what they do seem to expect. A modern full-dress textbook of medicine, surgery, or obstetrics will show how extravagant our expectations already are. These subjects must be stripped to their essentials, and further knowledge upon any one of them acquired after graduation. If new matter is to be introduced into the curriculum, some of the old must go, so that the final reformed scheme asks even less factual knowledge than we now demand; but what we do ask of this kind must be more fully co-ordinated and coherent, and informed by sound general principles. Notions of the critical importance of their own special aspects of medicine that may be urged by enthusiasts must not be allowed to rush us into a new and even worse crowding of the curriculum than we at present see.

For example, in the realm of psychological medicine the content of both normal and clinical psychology is highly charged with controversial matter: conflicting hypotheses

compete for recognition as generalizations of the facts of observation, and these "facts" are not always clearly distinguishable from assumptions. Psychology is in a ferment, and we must not plunge the student into the fermenting-vat. The exponents of this field of medicine must first put it in order and lend it coherence before psychological medicine can hope—or ask—to take its proper place in medical education. This is not to say that the present place taken by it in the curriculum is adequate, but to suggest that a wise infusion of medical education by the principles of psychological medicine demands something more fundamental than the compilation of a long list of titles of lectures and appointments to be crammed into an already overloaded course.

### Essentials of Reform

Similar considerations must determine and limit the requirements of other special branches of medicine. Each must be subordinated to the balance and moderation we wish to see in a new scheme of medical education. In short, the essentials of reform in medical training may be summarized as follows:

(1) A carefully thought out pruning of the amount of factual knowledge we seek to impart, ruthlessly undertaken in order that

(2) the student may be enabled to develop a more thoughtful and critical attitude, and a deeper understanding of the causes and manifestations of disease.

(3) An explicit recognition of the necessity of a leaven of theoretical medicine, side by side with its vocational aspects, and the provision of a category of teachers who shall develop it.

To these ends every branch of medicine must be prepared to make some sacrifices, so that we shall turn out thoughtful and discriminating graduates, capable of handling the unending flow of new experiences that must come to them in the practice of their profession, and capable also of independent judgment. On this sound stock we can always graft a higher order of knowledge in any desired branch of medicine.

The considerations put forward in this article, and thus summarized, will be familiar to all readers of Sir Thomas Lewis's volume of addresses entitled *Research in Medicine*. In these the fundamental principles of medical education, and the qualities and outlook of the teachers of medicine, theoretical and vocational, are discussed more amply and with more authority than I can command. No one who bears any responsibility for the reform of medical education can rightly ignore the principles laid down and expounded in these addresses.

### Conclusion

There are, of course, other aspects of the total problem of medical education not dealt with in this summary expression of a point of view: for example, the type of general education best fitted for the future medical student; the status and categories of teachers we shall need; the better organization of clinical teaching, and the necessity for a drastic reform of our present chaotic and purely vocational examination system. In respect of the last-named, the gross disorganization of the precious last year of the student's clinical training by the haphazardly instalments of the Conjoint Finals would defeat any system of teaching.

In short, the problem is a most complex one, and can be solved only when we have formulated the general principles of a reform of the curriculum and of our methods of teaching. The immediate and urgent issue here raised is the necessity for avoiding another patchwork and compromise revision of medical training and the swamping of the student by the addition to his burdens of fresh requirements from new branches of medicine, or from old branches that have taken new names and adopted new slogans. It would be folly to assume that this danger does not exist. The increasing and inevitable specialization in medicine has called into existence sectional interests nearly all striving for what they regard as adequate recognition for themselves, and it is the growth and momentum of these interests that may well threaten the drawing up of a new and rational plan of medical education.

In 1932, in the columns of this *Journal*, Dr. Charles Wilson, as he then was, wrote an article, entitled "The Student in Irons," in which in clear and admirable terms he laid bare

the defects of the content and methods of our teaching of the medical student. Therein he presented, more lucidly than I can hope to do, the aims that should inspire us in any reform. A brief citation from that paper may be allowed.

"It is nowhere denied that we ask impossible tasks of students, who are bewildered by hours of listening, and that we stamp out the habit of reflection by a ceaseless drill. And this is done in the name of education. . . . So strange an anomaly may set us thinking how we are come to such a pass. The blunt truth would appear to be that the handling and revision of the curriculum are based on a misconception of what we can and ought to attempt in a medical school. The one purpose of the student's years is, it seems, not to train and test habits of thought, but to collect and store a set of facts, as squirrels hoard the nuts on which they hibernate. . . . It may be conceded that such a policy was reasonable when medicine was a slowly progressing science that did not greatly alter in a man's lifetime. To-day it leaves him bankrupt when he has scarcely begun. The little he knows is soon antiquated, and he cannot keep up with a rapidly changing science, for we have so contrived to educate him that he cannot educate himself. . . . We trust neither his industry nor his capacity. He must be driven into different pens for every hour of the day, along with a drifting flock that presses now this way and now that. And this, if I may be allowed to change a metaphor, in the hope that he may one day recognize a disease because he has seen it before."

Surely, this analysis goes far more deeply into the problem than do the two reports we have considered, and shows a recognition of the total requirements of a medical education that is absent from them.

If now we are to content ourselves with a so-called reform that attempts no more than to fit still more into the medical course on the pretext that medicine is enlarging its scope, we shall have betrayed the medical student of the future, and shall have failed to do what is now possible to build a science of medicine with its own body of first principles and its own grammar.

## PETHIDINE AS AN OBSTETRIC ANALGESIC A REPORT ON 150 CASES

BY

BEDELIA GALLEN, M.B., Ch.B., D.P.H.

### Pharmacology of Pethidine

Pethidine (also known as dolantin, dolantal, and demerol) is the name given by the General Medical Council to the hydrochloride of the ethyl ester of 1-methyl-4-phenylpiperidine 4-carboxylic acid, which was synthesized in 1939 by Eisleb and Schaumann in a search for atropine derivatives. The chemical relationship of pethidine to atropine is seen in the following formulae:

Unlike morphine it is a relatively simple compound, although on close inspection of the formula some remote chemical similarity can be discerned between pethidine and morphine: thus both possess a piperidine ring.

The early clinical and pharmacological work on pethidine was done on the Continent, although most of the publications since 1940 are inaccessible owing to the war. It is claimed that clinically it is an outstanding analgesic, midway in action between morphine and codeine. Its analgesic action has been studied by Climenko, Homburger, and Barlow (1943), using the Hardy, Wolff, and Goodell (1940) technique, which consists in measuring the pain threshold of the skin to varying intensities of thermal radiation from a lamp. It was shown that 100 mg. by mouth raised the pain threshold by 50% for as long as six hours. By this method Batterman and Himmelsbach (1943) have shown that 50 mg. of pethidine intramuscularly is twice as potent as 22 mg. of codeine, and that 100 mg. parenterally approximates in analgesic potency to 1/16 gr. of morphine.

It is stated that pethidine is unique in possessing a morphine-like analgesic action, as well as being effective as a spasmolytic and sedative. Its pharmacology has been extensively investigated by Duguid and Heathcote (1940), Schumann (1940), Gruber *et al.* (1941), and Barlow (1943). The spasmolytic effect has been attributed to a direct depressant action on smooth muscle resembling that of papaverine, and to an atropine-like action on the parasympathetic nerve endings. It is more effective than papaverine in depressing smooth muscle, but less active than atropine. It relieves visceral pain not only by raising the pain threshold but by relaxing smooth muscle. Intubation studies by Batterman (1943) have demonstrated the spasmolytic effect of pethidine on the human stomach, pylorus, and small and large intestines. Animal experiments have yielded conflicting results, depending on the species used, on the technique employed, and on whether the organ was isolated or *in situ*. The spasmolytic effect of pethidine on the human ureter has been demonstrated by Climenko and Berg (1943).

The sedative effect of pethidine, which is more pronounced when given parenterally, is definite but not as marked as that of morphine. Rovenstein and Batterman (1943), who have used pethidine as a post-operative sedative, consider that the effect of 100 mg. hypodermically is equal to that produced by 1/4 gr. of morphine. After large doses sleep and drowsiness may occur, particularly after parenteral administration, but this is of short duration and less than the period of analgesia, and the patient can be easily aroused (Batterman, 1943). The effect wears off in two hours, although if the drug is given at night or to relieve pain sleep may be prolonged. Unlike morphine, pethidine does not produce a state of amnesia.

**Effect on the Uterus.**—Studies on the effect of pethidine on uterine muscle are conflicting. According to Dreyer (1943) it relaxes the intact and excised uterus; but this is denied by Gruber *et al.* (1941), who claim that in the dog it stimulates the intact and excised organ. This opinion is shared by Yonkman *et al.* (1943). Solomons and Widdess (1943) also state that it stimulates the guinea-pig and rabbit uterus *in vitro*. Using the balloon technique of Chassar Moir, they report that pethidine causes a slight increase in the tone and frequency of contraction of the human uterus *in vivo*. Care must be taken in interpreting clinical results with the balloon technique, as the introduction of a foreign body such as a balloon into the uterine cavity may produce reflex contractions. Woodbury (1943), using this technique, found that pethidine had no effect on uterine contractions in the human pregnant uterus. The effect of any drug on the uterus, animal or human, depends on the blood supply and stage of proliferation of the organ, which in turn depend on the oestrogen and progesterone tide. Thorp (personal communication) states that pethidine enhances the contraction of the rabbit uterus treated with pituitary extract in the oestrogenic phase, but relaxes it after contraction with adrenaline; in the progesterone phase pethidine has no effect. According to Thorp pethidine has no effect on the muscle tone of the uterus of the pregnant cat. In the following study it was evident that pethidine exerted a definite antispasmodic action on the cervix during labour.

#### Clinical Studies in Labour

The study was made because the unique properties of pethidine that have been reported—its combined analgesic, antispasmodic, and sedative actions—suggested that it might be a

very useful drug for producing obstetric analgesia. Also the fact that it is less of a respiratory depressant than morphine (Batterman, 1943) should render it safer for the baby than the latter, the dangers of which are well known. The reported absence of mental depression, urinary retention, and constipation following the administration of pethidine (Batterman, 1943) also appears to be a definite advantage, as these symptoms are commonly produced by morphine. Lastly, the relatively high margin of safety compared with morphine permits repeated dosage. The possible future shortage of morphine also makes the clinical evaluation of the newer analgesics imperative.

Since this study was begun two publications on pethidine as an obstetric analgesic have appeared in America, where the drug is known as demerol. Gilbert and Dixon (1943) report that in doses of 100 mg. to 400 mg. it noticeably shortens the time of labour in primiparae. The average dose was 300 mg. Adequate analgesia without amnesia was obtained by 72% of the patients; in combination with a barbiturate satisfactory amnesia was experienced by 61%. No adverse effects were observed on mother or baby. Roby and Schumann (1943) gave pethidine intramuscularly in doses of 100 mg. in combination with scopolamine to women in labour as soon as pains began. Satisfactory amnesia was produced in 85% of the cases; 14% of the babies needed some form of resuscitation.

#### Selection of Patients; Administration; Dosage

**Clinical Material.**—The series treated with pethidine reported here consisted of 150 cases. Detailed records were kept on the first 100 cases only. Of these, 53% were placid and not apprehensive; 47% were nervous and apprehensive. One of the latter group had a spastic cervix which dilated satisfactorily under the influence of pethidine, but required forceps delivery. Another had a rigid cervix, which failed to dilate and necessitated lower-segment Caesarean section. The 100 cases recorded comprised 70 primigravidae and 30 multigravidae, and all were apparently normal on medical and obstetric examination.

**Method of Administration.**—Oral administration, which was tried at first, was found to be unsatisfactory on account of the frequency of vomiting and the slowness of action. Roby and Schumann also found the oral route unsatisfactory. It was observed that it took from 20 to 60 minutes for the maximum analgesic effect to be produced by mouth. Pethidine was therefore given either intramuscularly or intravenously, or by the combined routes. Of the 70 primigravidae, 33 received the drug solely by intramuscular injection, while 37 were given both an intramuscular and an intravenous injection. Of the 30 multigravidae, 20 were given the drug intramuscularly, and 10 received it intravenously with or without an accompanying intramuscular dose.

**Dosage and Times of Administration.**—Two dosage schemes were tried:

(a) A total dose of 200 mg. of pethidine was given intramuscularly either alone or in combination with the stock mixture used in the labour ward (see Table I) or else with scopolamine gr. 1/150. The pethidine was given in two doses of 100 mg., one an hour after the other. The second injection was given either alone or with the stock mixture or scopolamine. In cases in which the first stage of labour was prolonged for more than 8 to 10 hours after the first injection of pethidine further injections were given, up to a total of 400 mg. in 24 hours. Gilbert and Dixon (1943) gave up to a maximum of 650 mg. in the same period. It was exceptional in our series to give more than 200 mg. The average time taken for the production of analgesia after intramuscular administration was 15 minutes, and the duration of action 3 to 4 hours.

(b) In order to obtain a more rapid effect some cases received pethidine intravenously. A dose of 100 mg. was given initially. This acted in 5 to 10 minutes. An hour later another 100 mg. was given intramuscularly, either alone or in combination with scopolamine gr. 1/150. The duration of action was 3 to 4 hours. If the first stage of labour was prolonged for more than 8 to 10 hours after the initial dose further injections of 100 mg. were given intramuscularly up to a total of 400 mg. in 24 hours.

Vomiting and other unpleasant side-effects may occur if pethidine is given rapidly by the intravenous route. This was minimized by asking the patient to close her eyes and by taking five to ten minutes over the injection. Ideally, the first injection of pethidine is best given when the cervix is

two fingers dilated and the patient is having regular contractions. Although pethidine does not depress respiration to such an extent as morphine, it would appear that it is not wise to give it within 2½ hours of the expected delivery of the child. This figure compares favourably with that of four hours for morphine. Many of the patients receiving pethidine actually slept during labour.

#### Evaluation of Analgesic Effect

The degree of analgesia produced in the first 100 cases compared with controls receiving the stock mixture used in the labour ward (chloral hydrate gr. 30, potassium bromide gr. 30, tinct. opii m. 10) was as follows:

Degree of Analgesia	Pethidine Cases	Control Cases
Complete	10	0
Satisfactory	50	10
Fair	34	90
Nil	5	0
Amnesia	1	0
	100	100

These figures refer to the first stage of labour only, as in most cases Minnitt's gas-and-oxygen apparatus was used to complete the second stage of labour.

In only one case in this series—a young primigravida—was amnesia produced. Initially she was given morphine gr. 1/6 and scopolamine gr. 1/150, followed by 100 mg. of pethidine intramuscularly, which was repeated twice, and a further dose of scopolamine gr. 1/150. Intermittent chloroform anaesthesia was administered at the end of the second stage. It is of interest to record that the duration of labour from the time of administration of the morphine-scopolamine was 5½ hours. Roby and Schumann (1943) obtained satisfactory amnesia in 85% of their cases. A dose of 100 mg. of pethidine was given intramuscularly, followed by scopolamine 1/100 gr. A further injection of scopolamine gr. 1/200 was given an hour later, and in the case of primiparae repeated every one to five hours.

#### Effect on Duration of Labour

Table I gives the average duration of labour, in hours, of the various groups, the interval between the initial dose of pethidine and the birth of the child, the interval between the final dose of pethidine and the birth of the child, and the average duration of the third stage in minutes.

TABLE I

Medication	Parturient	No. of Patients	Route		Average Duration of Labour (hours)	Average Time between Initial Dose and Birth (hours)	Average Time between Final Dose and Birth (hours)	Average Duration of Third Stage (min.)
			i.m.	i.v.				
Pethidine with or without stock mixture*	P	59	26	33	20-70	7-21	5-34	20
Pethidine and scopolamine	M	23	15	8	16-47	5-09	3-18	20
Patients receiving stock mixture only	M	11	7	4	15-95	9-66	6-76	14-5
	M	7	5	2	16-89	5-90	5-30	15-5
	M	70			18-81			18-9
	M	30			10-74			17-8

\* The stock mixture contained chloral hydrate gr. 30, pot. bromide gr. 30, tinct. opii m. 10, aq. chloroformi ad 1 oz.  
† P—Primiparae, M—Multiparae.

On examining this table it would appear that labour was prolonged in those patients receiving pethidine, in comparison with controls not receiving the drug. This apparent prolongation of labour was in our opinion due to the high proportion (47%) of apprehensive and nervous women in the selected cases. The actual duration of labour, however, from the time of administration of the pethidine in both primigravidae and multiparae falls well within, if not below, average time limits. Gilbert and Dixon (1943) report that in their series pethidine noticeably shortened the duration of labour in primiparae, and Roby and Schumann (1943) state that the drug does not prolong labour.

#### Instrumental Delivery

The use of pethidine did not appear to increase the incidence of instrumental delivery. In this series forceps were used in 10% of all cases, but there was always a good obstetric reason

for this. In only one case was there weakening of uterine contractions necessitating the application of forceps. The incidence of instrumental delivery in the control group receiving pethidine was 13%. The reasons for the use of forceps in the two groups were as follows:

Reason for Forceps	Pethidine Cases	Control Cases
Contracted outlet	5	2
Deep transverse arrest	1	4
Extreme nervousness and rigid perineum	1	0
Extreme nervousness and lack of co-operation	2	2
Weak uterine contractions and rigid perineum	1	1
Maternal distress	0	2
Foetal distress	0	1
Threatened uterine inertia	0	1
	10	13

#### Obstetric Complications

The use of pethidine did not increase the incidence of obstetric complications, of which there were three. Two were cases of retained placenta and one a rigid cervix. In one instrumental delivery the placenta was retained, but was successfully expressed by Credé's method. In no other case in the series was there any weakening of the contractions, and hence there has been no tendency to post-partum haemorrhage. On the contrary, it was observed that in a case in which pethidine had been used placenta and membranes were much more liable to come away complete from the uterus. In the second case of retained placenta the latter was adherent to the uterus, necessitating manual removal, but in this instance there was a history of a retained placenta in a previous delivery. In the case of the rigid cervix, in spite of a labour prolonged for 48 hours, and the use of morphine, scopolamine, and pethidine, the cervix failed to dilate, and lower-segment Caesarean section had to be performed in the interest of mother and child.

It would appear that pethidine exerts a definite antispasmodic effect on the cervix, particularly in the clinical entity spasmodic cervix, in the treatment of which it is superior to morphine.

In the control group obstetric complications occurred in 2%. Both were cases of post-partum haemorrhage from a relaxed uterus due to weak contractions.

#### Reactions in the Mother

The commonest toxic manifestation in the mother was vomiting, which occurred in 28% of the cases. As previously stated, oral administration was discontinued because of vomiting and delayed action. It was also observed that a transitory rise in blood pressure of some 10 to 20 mm. systolic and/or diastolic was fairly common within 15 minutes of administration. This rise of blood pressure did not last for more than 30 to 60 minutes. No association between vomiting and rise of blood pressure was established. On account of the possible rise in blood pressure pethidine was not given to cases complicated by toxæmia or hypertension. Other untoward symptoms often observed, particularly after intravenous injection, were dizziness, tingling of the limbs, vertigo, and dryness of the throat. In no case was excitement observed. The frequency of vomiting following intravenous injection was effectively reduced by injecting the pethidine very slowly over a period of five to ten minutes, while requesting the patient to keep her eyes closed.

#### Condition of Babies

Of the 100 babies born to mothers receiving pethidine 91 were apparently normal and active at birth, and 9 were slow—i.e., required resuscitation measures. These figures are similar to those of Roby and Schumann (1943). There were two deaths, due respectively to a tentorial tear and a prolapsed cord. The neonatal morbidity for the first three days after birth was nil. Seven of the babies were cyanosed and 7 suffered from respiratory depression. Slight impairment of pulsation was noted in 9 babies and poor muscle tone in 8. In no case did any of the babies fail to respond to routine methods of resuscitation for the newborn, crying well within at most 20 to 30 minutes of birth and responding to stimulation.\*

\* In the control group given the chloral-bromide-opium mixture there were 2 slow babies. One was limp, but responded quickly to treatment. The other was blue, and went into white asphyxia; it recovered with treatment.

In respect of the 9 slow babies Table II shows the dose of pethidine and the time between its administration and the birth of the child.

TABLE II

Parity	Degree of Dilatation of Cervix on Initial Dose	Initial Dose	Time of Initial Dose before Birth	Final Dose	Time of Final Dose before Birth
1	4 fingers	100 mg. i.m.	2 hrs. 10 min.	100 mg. i.m.	30 min.
1	3 "	100 mg. i.m.	55 min.	—	—
1	3 "	100 mg. i.m.	2 hrs. 25 min.	100 mg. i.m.	20 min.
0	Anterior lip	100 mg. i.v.	20 min.	—	—
0	3 fingers	100 mg. i.v.	2 hrs.	—	—
0	3 "	100 mg. i.v.	2 hrs. 15 min.	100 mg. i.m.	1 hr. 5 min.
0	3 "	100 mg. i.v.	2 hrs. 35 min.	100 mg. i.m.	1 hr. 10 min.
0	3 "	100 mg. i.v.	2 hrs. 25 min.	100 mg. i.m.	1 hr. 25 min.
0	4 "	100 mg. i.m.	3 hrs. 15 min.	100 mg. i.m.	1 hr. 15 min.
0	—	scopolamine gr. 1/150	—	scopolamine gr. 1/150	—

In all these cases the progress of labour was much quicker than was anticipated clinically. From experience with them it was decided that it is undesirable to administer pethidine within 22 hours of the expected delivery of the child. The average time between the final dose and the end of labour in Gilbert and Dixon's cases was 2 hours 22 minutes in primiparae.

#### Summary

In the dosage employed pethidine is an effective obstetric analgesic. It does not, however, produce amnesia unless given with adequate doses of other drugs—e.g., scopolamine and barbiturates.

Only 5% of the patients failed to obtain any relief from pethidine. Analgesia was complete or satisfactory in 60%.

Two dosage schemes were found to give satisfactory results: a) Initial dose 100 mg. intramuscularly, repeated one hour later with a chloral-bromide-opium mixture or with scopolamine; b) 100 mg. pethidine intravenously, followed by 100 mg. intramuscularly an hour later, either alone or with scopolamine gr. 1/150. In either technique further intramuscular injections of 100 mg. can be given up to a total of 400 mg. in 24 hours. The first injection is best given when the cervix is two fingers dilated and the patient is having regular contractions.

Pethidine and scopolamine form an effective combination for producing obstetric analgesia.

Given intravenously pethidine produces analgesia in 5 to 10 minutes; intramuscularly in 15 minutes. The duration of action is 2 to 4 hours. Intravenous administration produces a more rapid and powerful initial action, but intramuscular administration is highly satisfactory and equally effective. Intravenous administration is contraindicated in labour complicated by toxæmia or hypertension. Pethidine has a definite antispasmodic action on the cervix.

Statistically, in comparison with controls pethidine appeared to prolong labour. This was probably due to the selection of the cases. The figures compare well with average figures for the duration of labour.

No increase in the incidence of instrumental delivery or obstetric complications was associated with the use of pethidine.

Reactions in the mother included vomiting, a temporary rise of blood pressure, dizziness, tingling of the limbs, and dryness of the throat. These were transient, and, although unpleasant, gave no cause for alarm.

Of the babies 91% were apparently normal and active at birth; 9% were slow, and required resuscitation.

There were no deaths among the babies that could be attributed to pethidine. The neonatal (three days) morbidity was nil.

This investigation was carried out in the obstetric unit of St. Mary's (L.C.C.) Hospital, Kensington, from Jan., 1943, onwards. Thanks are due to the consultant obstetrician, Mr. W. C. W. Nixon, for his helpful criticism of the investigation and the manuscript.

## OBSTETRIC ANALGESIA WITH PETHIDINE

BY

WALTER SPITZER, M.D. Prague, M.R.C.S., L.R.C.P.  
 Senior Resident Obstetrician, Kingston County Hospital, Surrey

Pethidine hydrochloride has been studied in our maternity department since Oct., 1941, in regard to its analgesic and spasmolytic effects on normal labour. It is a pain reliever of fairly recent introduction, the hydrochloride of the ethyl ester of 1-methyl-4-phenylpiperidine-4-carboxylic acid, discovered by Eisleb and Schaumann in their search for an ideal analgesic with spasmolytic atropine-like properties. The drug is known on the Continent as "dolantin" and in the United States as "demerol," and was officially named pethidine by the G.M.C. a year ago.

The pharmacological virtues and faults of pethidine have been carefully surveyed by Rothschild (1941) of Basle. It possesses a powerful analgesic action like that of morphine, but is stimulating rather than depressing to the central nervous system. Because of its depressant effect on smooth muscle tissue its spasmolytic properties have been compared to those of atropine and papaverine. Several authors have claimed that it can antagonize the effects of acetylcholine and histamine on the intestine (Eisleb and Schaumann, 1939; Duguid and Heathcote, 1940; Schaumann, 1940). Gruber *et al.* (1941) could not acknowledge the spasmolytic action. It is relatively non-toxic, and has little effect on the pulse rate or the pupil. It lowers the blood pressure and depresses the respiration only in large doses.

Only a few clinical reports on pethidine are available in this country. Prof. Christie (1943) undertook an investigation on behalf of the War Wounds Committee of the Medical Research Council. Pethidine proved to be of value as an analgesic when given by the mouth to 335 patients of six different hospitals. Of the patients with "severe pain" 55% obtained complete relief and 20% partial relief; of those with "moderate pain" 61% were completely and 12% partially relieved. Toxic symptoms were uncommon and never serious. Fitzgerald and McArdle (1943) described the usefulness of pethidine in neurological cases.

The Continental literature on pethidine in a variety of conditions is very encouraging; and as regards obstetrics, Benthin (1940, 1942), Fuchs (1941), and Sonnek (1941) have described excellent results in the relief of pain in labour. Detailed literature is not accessible in this country.

It seemed to me to be advisable to investigate another method of inducing analgesia in the first stage of labour which would cover three important points—namely, (1) reduce pain without having a depressing effect on the respiration and circulation of mother or baby; (2) avoid psychic depression; (3) avoid prolongation of labour. The choice of obstetric analgesics in any particular case has often to be made according to existing conditions. That is why an ideal method has not yet been agreed upon and legions of analgesic and anaesthetic substances in a variety of methods of administration are used all over the world. The exhaustive studies of obstetricians in this country have shown that "twilight sleep" is, for the baby, a dangerous first-stage treatment. All general anaesthetics weaken uterine contractions and retraction. The barbiturates depress the prothrombin levels in mother and child by causing damage to the liver, in which prothrombin is formed (Browne, 1942; Fitzgerald and Webster, 1942). Barbiturates are sometimes responsible for delay, with deleterious effects on the third stage of labour.

In domestic practice chloral hydrate and bromide and/or morphine are still most commonly used. While the first two drugs are safe and fairly satisfactory, the use of morphine for analgesia is unsafe for both mother and baby. It is encouraging that Eardley Holland (1943) has reminded the profession again of the dangerous effects of morphine as regards the respiration of the foetus. Especially in the present era, in which there is an increase in the number of premature labours, the liability to primary apnoea and atelectasis or pneumonia after use of morphine or the popular derivatives has to be taken into account. In short, all narcotics depress the respiratory centre of the foetus far more than that of the mother, and occasionally

from hopeless malignant disease. The cannula shown in the accompanying illustrations can be regarded as fool-proof provided the simple technical details given below are followed.

### Technique

The patient lies prone. A wheal of local anaesthetic is raised on the skin in the middle line just above the manubrio-gladiolar junction. Using a large but short hollow needle, the point is driven right on to the bone and about 2 c.cm. of 1% solution of novocain is infiltrated. This subperiosteal infiltration is an important detail. The area is then massaged with a swab so as to disperse the anaesthetic and enable one to feel the manubrio-gladiolar synchondrosis. The trocar and

the tip of the cannula into the marrow cavity is undeniable more citrate is injected and the syringe is disconnected. Quickly the cannula is linked with the infusion or transfusion unit, the tubing of which has been previously demonstrated to be free from air-bubbles. Strips of adhesive plaster of appropriate width are used to fix the wings to the chest wall and narrow strips of the same material are placed to steady the attached tubing at the correct angle (Fig. 4).

Spectators unfamiliar with the method invariably remark (a) how painless is the procedure; (b) how easily fluids gravitate into the medulla—they liken the rate of gravitation (before it has been damped down) to that expected after entry of a large unobstructed vein.

FIG. 1.—The trocar and cannula about to enter the manubrium.  
FIG. 2.—The medullary cavity entered.

FIG. 3.—Having injected a small amount of citrate solution, the piston is withdrawn, and if red marrow is easily and liberally aspirated the extremity of the cannula is correctly placed within the marrow cavity. This step is fundamental.

cannula is inserted just above this ridge (Fig. 1) and pointed almost directly downwards towards the floor, but with a very slight inclination towards the patient's head. An unhurried boring motion is imparted to the instrument. The pressure, at first slight, is increased. The feeling that the outer plate has been penetrated is unmistakable. Penetration being accomplished, the angle of the instrument is altered and the point is directed towards the patient's head. The wings do the rest—they ensure that the correct depth has been reached, they set the correct angle, and they prevent too deep penetration (Fig. 2). The trocar is removed. The next step is to take a 10- to 20-c.cm. Record syringe half full of sodium citrate solution, which is in readiness. The syringe is affixed to the cannula and some of the citrate solution is injected. The piston is withdrawn. If what appears to be blood (it is red marrow) is easily and liberally withdrawn so that it colours the whole of the contents of the syringe (Fig. 3) the extremity of the cannula is correctly placed within the marrow cavity. If the flow of marrow is not entirely free, the trocar is reinserted into the cannula, which is then very slightly withdrawn and another attempt to aspirate marrow is made. When entry of

FIG. 4.—The cannula is linked to the infusion apparatus.

For want of ocular demonstration, generations of surgeons have suspected that too often broken bones are filled not with red marrow but with black ingratitude. It may well be that the rising generation will verify almost daily that even in old age the normal sternum is full of marrow so red and so fluid that on macroscopic acquaintance it is indistinguishable from freshly drawn blood.

Mr. P. Regen of Messrs. Willen Bros. not only has carried out the making of the trocar and cannula, but by his enthusiasm and knowledge has been largely responsible for the present state of its development. Several features of the instrument, notably the large-handled trocar, were devised by Mr. T. W. Pearce, biochemist at the Dryburn Hospital, Durham. My former house-surgeon, Mr. L. D. Miller, is still investigating, on the living and in the post-mortem room, the depth of the marrow compartment from the skin overlying the sternum. As a result of these investigations it is possible that the instrument may be improved still further.

Major F. M. Burton, M.D., F.A.C.S., U.S. Army Medical Service, has helped me with gravity blood transfusions by this route.

## STAPHYLOCOCCAL SEPTICAEMIA TREATED WITH SULPHADIAZINE

BY

H. BATHURST NORMAN, G.M., D.M., M.R.C.P.

*Major, R.A.M.C.; Medical Specialist*

The chemotherapy of staphylococcal septicaemia by means of drugs of the sulphonamide group has been disappointing. In a study of the efficacy of the newer derivatives of this group Kolmer and Brown (1942) conclude that the chemotherapy of staphylococcal infections is unsatisfactory and is certainly inferior to similar therapy applied to haemolytic streptococcal and pneumococcal infections. Reimann (1942), after an exhaustive review of published cases, is of the same opinion. The treatment of choice for these infections is by means of penicillin. Unfortunately penicillin is not yet available for general use, and until supplies are forthcoming the sulphonamides remain the most hopeful therapeutic agents.

In the case here recorded sulphadiazine showed itself to be remarkably efficacious. Finland, Peterson, and Goodwin (1942), who have compared the efficacy of various preparations of sulphonamides, treated five cases of staphylococcal septicaemia with sulphadiazine. The average total dose given was 147 g. They claim a good therapeutic response in one case and a doubtful response or good initial response with relapse in the other four. It should be noted that, of these four, one was complicated by pyonephrosis and three by osteomyelitis. There were no deaths, but the cases complicated by bone involvement needed surgical drainage before chemotherapy was effective. These authors conclude that the efficacy of sulphadiazine is probably similar to that of sulphathiazole, but its lower toxicity makes it the drug of choice, particularly when prolonged therapy is desirable. In the present case sulphadiazine was not used until sulphathiazole had proved to be ineffective.

### Case History

The patient, a soldier 32 years of age, was admitted to a military hospital on Feb. 23, 1943, complaining of aching in the limbs and malaise for one week. His health previously had been good, but a fortnight before the onset of his illness he had had a boil on the back of his neck which had been treated with hot fomentations and vigorous expression of pus. During several days before admission he had felt unwell and feverish, and was thought to have an influenza attack. There had been some cough with blood-stained sputum, and heavy night sweats had been troublesome. The bowels had been constipated. He complained also of a tender lump over the left scapular angle that was painful when he sat back against his pillows. There had been no known contact with any infectious disease.

On examination the temperature was 101° F. and pulse rate 115. There was no evident anaemia, but the lips had a cyanotic tinge. The throat and teeth were in good order. The lungs showed no obvious abnormality. The cardiovascular system was normal and the blood pressure 130/95. The spleen could not be felt. No abnormality was found in the central nervous system. There were tender nodules at the angle of the left scapula, in the right lumbar region, in the groins, on the abdominal wall, in the right thigh, and on the inner aspect of the left knee. Some of these were acutely tender, and over several the skin was reddened. The urine was acid in reaction, with no sugar or albumin, and the deposit contained a few leucocytes and epithelial cells. The blood count on admission was: haemoglobin, 84%; red blood cells, 4,690,000 per c.mm.; colour index, 0.91; white blood cells, 14,000. The sputum contained no tubercle bacilli, but was blood-stained.

The patient was put on full doses of sulphathiazole. On March 2 a fresh crop of nodules appeared, a hectic temperature persisted, and his general condition was very poor. A differential white cell count gave a total of 20,700, with 78% polymorphonuclear cells. Blood culture proved sterile, but pus from a fluctuant nodule on the left arm was reported on as follows: "Smears: Large numbers of pus cells and clusters of Gram-positive cocci, morphologically staphylococci. Culture: Profuse growth of *Staph. aureus*." X-ray examination of the chest showed a "right basal pneumonitis."

By March 9 the patient's condition had still further deteriorated. There was no abatement in the fever and he had developed an ulcer on the right cornea. Several of the abscesses were fluctuant, and from two of them a small amount of thick pus was aspirated. A few petechial spots were noted on the trunk. A large, deep, and very tender abscess developed in the muscles of the right thigh, and

there was acute pain with local tenderness in the region of the left elbow; but radiographs of the joint and of the right femur were negative. The white blood cell count was 16,600.

On the following day a shower of emboli occurred over the lower extremities, giving the picture of an extensive macular rash. The temperature was at this time 103.5° F. and the pulse rate 145. On March 13 sulphathiazole was stopped, a course of 60 g. having been completed without obvious benefit. The administration of sulphadiazine was then begun. After 48 hours the temperature was normal, and the patient's comment was: "I feel quite different. I did not expect to feel as I do now in six months' time." A blood count showed: haemoglobin, 82%; red blood cells, 4,690,000 per c.mm.; colour index, 0.9; white blood cells, 22,000, 77% being polymorphonuclears.

The temperature did not settle altogether, and a slight evening rise persisted, but the general improvement in well-being was maintained and there were no further embolic phenomena. The white cell count on March 17 was 11,600, and on March 25 14,200. At this time sulphadiazine was stopped after a total dosage of 100 g. The patient's general condition was now fairly satisfactory. Pathological examination of the urine had been repeatedly negative. The haemoglobin was 82%, and the leucocyte count on April 1 was 13,600. A large indurated swelling of the right thigh was still present, causing much pain and discomfort. A further radiograph of the right femur was negative. By April 13 this swelling had become more localized, with a suggestion of central fluctuation. The haemoglobin and white cell count were unaltered. There was no further rise of temperature. On April 20, in view of the prolonged septic infection and moderate degree of anaemia, one pint of fresh compatible blood was given by intravenous transfusion. Haemoglobin was 96% after transfusion. On May 4 the abscess in the right thigh was aspirated, 3 c.cm. of blood-stained serous fluid being withdrawn; this was sterile on culture. Convalescence thereafter was uneventful.

### Summary

A case of staphylococcal septicaemia is recorded in which a dramatic response was obtained with sulphadiazine after sulphathiazole had proved ineffective. Since penicillin, the drug of choice, is not generally available, optimum use must be made of the sulphonamides in treating this condition. Sulphadiazine is the preferable derivative of this group because of its low toxicity and its apparent greater efficacy.

My thanks are due to Col. A. D. Stirling for permission to publish this case.

## SPONTANEOUS RUPTURE OF ABNORMALLY MOBILE SPLEEN

BY

JAL DUBASH, M.D., D.C.P., D.T.M.&amp;H.

*Pathologist, E.M.S. Area Laboratory, Borough General Hospital, Ipswich*

AND

G. F. LANGLEY, Ch.M., F.R.C.S.

*Hon. Assistant Surgeon, East Suffolk and Ipswich Hospital*

Spontaneous rupture of the spleen in non-tropical countries is a very rare condition, and is known to occur occasionally in patients suffering from malaria or typhoid; a few cases of rupture of leukaemic spleens have been recorded. Zuckerman and Jacobi (1937) reviewed 28 cases of rupture of the normal spleen, but considered that only 21 of these could be accepted. In the case now reported a spontaneous rupture of the spleen occurred while the patient was in bed in hospital suffering from acute axillary lymphadenitis; subsequent examination showed only inflammatory changes in the spleen.

### Case Report

A soldier aged 35 was admitted to the Borough General Hospital, Ipswich, on Sept. 13, 1942, suffering from pain in the left axilla of 24 hours' duration. On the evening before his admission he complained of aches and pains all over the body and had vomited once. On admission the temperature was 101.6° F., pulse rate 95, and respiration rate 22. A few enlarged tender glands were felt in the left axilla; but no primary cause for this adenitis was found. He had been given 7 g. of sulphapyridine during the previous

day in a camp reception station. After admission he was given sulphathiazole by mouth and local treatment by short-wave therapy.

On Sept. 15 the patient suddenly collapsed. It was apparent that a severe intraperitoneal haemorrhage had occurred; a blood count was carried out and blood transfusion was given. The count showed: red cells, 3,800,000 per c.mm.; Hb, 60% (Sahli—standard 100% = 15.5 g.); white cells, 36,370 per c.mm.: myelocytes 3,700, metamyelocytes 6,600, neutrophil polymorphs 22,000, lymphocytes 2,590, eosinophils 370, mononuclears 1,110 per c.mm. There were no nucleated red cells: this was taken to be a response to severe haemorrhage. A pre-operative diagnosis was made of rupture of the spleen or of an intraperitoneal aneurysm, probably of the splenic artery.

At operation the peritoneal cavity was full of blood, five and a quarter pints being measured. The spleen was ruptured transversely at its convex border. Splenectomy was easily performed, as there were no adhesions and the splenic pedicle was unusually long. The patient collapsed during closure of the abdomen and died in spite of the usual resuscitation methods.

**Post-mortem Findings.**—The stomach contained a fair quantity of undigested food and some bright blood. The mucosa showed minute erosions, but no chronic ulceration. The sternal bone marrow was greyish red and hyperplastic. No other pathological lesions were found.

**Histological Examinations.**—Spleen:—No definite pathological change was noted in the sections, apart from evidence of acute inflammation. Sections were sent to Dr. A. H. T. Robb-Smith for his opinion. His report is as follows: "The spleen has the appearances, apart from actual trauma, of those found in a reaction to an acute inflammation, and it is likely to be an example of an acute inflammatory condition with an acute splenic tumour which has ruptured spontaneously." The weight was 280 g. Axillary lymph glands showed microscopical evidence of subacute lymphadenitis; this finding was confirmed by Dr. Robb-Smith. Bone-marrow films (taken immediately after death) revealed marked myeloid reaction, presumably due to inflammatory changes. The liver showed no abnormal changes.

**Past History.**—Steps were taken to trace the previous medical history of the patient. His Army record sheet showed that he had never been abroad. There was no history from the patient or from his unit of any injury within recent months. Apart from bronchitis he had had no other illnesses.

### Discussion

Zuckerman and Jacobi (1937) consider that minor degrees of torsion or of angulation of the splenic pedicle are sufficient to slow the circulation and to cause congestion of the spleen, resulting in rupture. They also consider that minor gastro-intestinal disorders may initiate the torsion or angulation and thereby cause the congestion and rupture. They found that the phrenico-splenic ligament is absent in about 2% of individuals; absence of this ligament is one of the causes of undue mobility of the spleen.

In the present case the serious condition of the patient prevented accurate anatomical investigation, but it was remarked at the time of the operation that the spleen was excessively mobile and thus splenectomy was a most simple procedure. It is therefore probable that the phrenico-splenic ligament was absent, and no restricting peritoneal bands were encountered. The patient had vomited before admission; this and the finding of food residue in the stomach, long after solid food had been taken, suggest that a gastro-intestinal disorder had developed. The presence of blood in the stomach may be attributable to obstruction of the vasa brevia by the same angulation or torsion that contributed to the rupture of the spleen. The presence of blood in the stomach and intestines has been reported in conditions of shock. The spleen in our case was not grossly enlarged; the structural changes were those representing the normal response of the spleen to a toxæmia and, as such, are to be expected in any acute inflammatory process. The rupture must therefore be regarded as being due to a mechanical process rather than to a pathological condition.

Ledderhose (1890) and Foucault (1923) considered that spontaneous rupture could occur only in a diseased spleen. Zuckerman and Jacobi have reviewed 28 cases of rupture of the alleged normal spleen, but accepted only 21 cases as genuinely normal. None of these was associated with acute inflammation. In their series spontaneous rupture occurred in 16 males and 12 females. The age incidence was: under 20 years, 2 cases; 20–30, 7 cases; 30–40, 6 cases; 40–50, 7 cases; 50–60, 5 cases. In 5 cases there was a history of epigastric distress related to meals, and in 5 cases the onset of

rupture was just after eating or drinking. Shock was noted in only 15 cases. Pain in the left shoulder was present in 3 cases and in the right shoulder in 1 case. Halliwell (1933) reported a case of spontaneous rupture of a normal spleen in which there was a long splenic pedicle. In Stretton's case (1926) rupture occurred in a female patient after coitus. In Susman's case (1927) the rupture occurred after the patient had bent down to lift a heavy object, and it was suggested that the contraction of the abdominal wall caused the rupture. Bohler (1933) reported a similar case occurring after the patient had bent to lift a heavy object. Abell (1933) recorded a case of rupture of a wandering spleen with torsion of its pedicle. In the cases described by Smith, Morrison, and Sladden (1933) and by Burnett and McMenemey (1935) splenomegaly was solely due to congestion, and in the former case pregnancy was thought to be a contributory factor.

In our own case the spleen was excessively mobile and rupture occurred at rest in bed. No gross pathological changes were discovered in the spleen beyond simple, inflammatory processes such as must exist in most septic conditions. Some gastro-intestinal disorder was indicated by the vomiting before admission and also by the post-mortem finding of undigested food residue in the stomach many hours after the preceding meal.

### Summary

A case of spontaneous rupture of an abnormally mobile spleen is described in which the rupture occurred while the patient was at rest in bed and in which there was no preceding accident.

A discussion of the causes of spontaneous rupture of the spleen and a review of the literature suggest that excessive mobility may subject the spleen to congestion by angulation or torsion of its pedicle sufficient to result in spontaneous rupture.

Our sincere thanks are due to Dr. Robb-Smith for reporting on the sections and for helpful criticisms.

## Medical Memoranda

### Achrestic Anaemia with Achlorhydria

Achrestic anaemia as first described by Israëls and Wilkinson is characterized by: (1) the findings of a macrocytic anaemia; (2) free HCl in the stomach contents; (3) a prolonged course which fails to respond to efficient anti-pernicious-anaemia therapy; (4) megaloblastic hyperplasia of the bone marrow; (5) the recovery of adequate amounts of the anti-anaemic principle from the liver. The aetiology is the failure to utilize the anti-anaemic principle or to mobilize it from the tissue stores.

Recently I have had under my care a case of achrestic anaemia differing a little from the above outline in that there was achlorhydria. Such a condition must be very rare.

### CASE HISTORY

A widow aged 56 was admitted to hospital, having complained for six months of dyspnoea, faintness, weakness of the arms and legs, extreme exhaustion, nausea, and vomiting. The symptoms were gradually getting more pronounced. Her appetite had been poor, but her weight was steady. She had received no previous treatment.

Examination revealed a pale woman who looked older than her years but showed no signs of wasting. The pulse was 100 and regular. The face was puffy and the teeth were carious. There were purpuric spots on the arms, chest, and abdomen, with oedema of the hands and feet. The tip of the spleen was just palpable, and the liver was enlarged 2 in. There were no enlarged lymph glands, and no other abnormality in the heart, lungs, C.N.S., or urine was detected. The blood count was: red cells, 715,000; white cells, 4,000; haemoglobin, 20%; colour index, 1.4. The film showed definite macrocytosis. Fractional test meals even with histamine revealed achlorhydria, with excess of mucus. The stools were always negative for occult blood.

The patient was immediately given one pint of citrated blood by the drip method. There was no reticulocyte response to intramuscular injections of hepalex, 10 c.cm. stat. and 5 c.cm. daily for two weeks, the reticulocyte count never going above 1%. This same hepalex gave good results in other cases of pernicious anaemia in the ward. She was repeatedly transfused, as transfusion seemed the only means of keeping her alive. She was given liberal allowances of ferrousol, redoxon, yeast, marmite, liveroid, venturulin, thyroid, and HCl dil. No one preparation or combination of preparations seemed to help. At times, quite independently of treatment, there were definite remissions, and on one occasion the haemoglobin rose to 58%. No cause for these remissions could be detected. During one of them her carious teeth were extracted, but even this did not appear to affect her progress.

After being treated for a year the patient died of bronchopneumonia. At the necropsy (by Dr. W. Whitelaw) the pathology of the intestinal tract was a chronic gastritis. The femoral bone marrow was extremely hyperplastic. The heart was not enlarged, and the myocardium was pale. The lungs gave the findings of bronchopneumonia. There was much free iron in the liver, kidneys, and spleen. On microscopical examination the bone marrow was seen to be megaloblastic.

This case presented most of the characteristics of achrestic anaemia, as there were the findings of a macrocytic anaemia, failure to respond to efficient anti-pernicious-anaemia therapy, and a megaloblastic hyperplasia of the bone marrow. Achlorhydria is certainly very unusual, but Israëls and Wilkinson (1940) have suggested that it might occur in achrestic anaemia, and state that they had one such instance. In my case the achlorhydria may have been due to the chronic gastritis, the result of dental sepsis. Unfortunately there were no facilities for testing the amounts of anti-anaemic principle in the liver, but there is enough evidence to substantiate the case without this.

I wish to thank Dr. John F. Wilkinson, Liverpool, for his help and advice; Dr. T. M. Anderson, medical superintendent, Dudley Road Hospital, Birmingham, for permission to publish the case; and Dr. W. Whitelaw, pathologist, Dudley Road Hospital, for his post-mortem findings.

A. A. HUSE, M.D., B.Sc., M.R.C.P.

Senior Physician, Dudley Road Hospital, Birmingham.

### A Proposal to Prevent Necrosis of the Tabula Externa of the Skull denuded of Periosteum

In extensive scalp wounds in which a large area of the skull is deprived of the periosteum the tabula externa undergoes necrosis unless it is covered by skin within a reasonable time. A free graft has very little chance of success in these circumstances because of the poor blood supply of the host tissue, and a pedicle graft may encounter technical difficulties. In my experience the following new method has been helpful:

Multiple burr-holes are made by a hand drill into the whole denuded area of the external table. The holes are 2 to 4 mm. in calibre and 15 mm. apart. They should penetrate into the diploe—a fact indicated by slight bleeding from the bone. In about 7 to 10

Drawing showing, at different stages, the granulations growing out of the diploe.

days granulation tissue originating from the diploe will appear through the holes and spread flatly over the tabula externa surface. The drawing shows the granulations at different stages. In a few days' time the granulations are sufficiently confluent to provide a good blood supply, and are then covered by a Thiersch graft. The graft is treated in the usual manner. The denuded area should be covered from the beginning with a 10% cod-liver-oil-vaseline ointment in order to prevent drying.

Whether this method would be useful or not in cases in which there is already some necrosis of the external table is not yet certain, and only future experience will show; but it is certainly worth trying.

D. ENGEL, M.D., F.R.C.S.Ed.,

Resident Surgical Officer, King George Hospital, Ilford.

## Reviews

### ENCEPHALOGRAPHY

*Encephalography.* By E. Graeme Robertson, M.D., M.R.C.P., F.R.A.C.P. Monographs from the Walter and Eliza Hall Institute of Research in Pathology and Medicine, Melbourne. No. 2. (Pp. 105. 32s. 6d.) Melbourne and London: Macmillan and Co.

The invention of encephalography, by which is meant radiography of the brain after the introduction of air by the lumbar route, put at the disposal of neurologists a diagnostic technique the value of which is still too little appreciated. Dr. Graeme Robertson's book would be of value; therefore if it did no more than bring home to the physician how much can be learned by means of encephalography when this is carried out by an expert.

Robertson gives a detailed account of his technique with a discussion of its anatomical basis. Encephalography carefully carried out may be expected to yield information about the contents of the posterior fossa, including the fourth ventricle, the aqueduct of Sylvius, the third and lateral ventricles, and the cerebral subarachnoid space. The author might perhaps have stretched his title enough to include a chapter on myelography, in which air is used in the diagnosis of obstructions of the spinal subarachnoid space. The value of encephalography in the diagnosis of intracranial tumour is well known. Dr. Robertson thinks that its usefulness in the diagnosis of post-traumatic headache and epilepsy has probably been overestimated, but it gives considerable help in the recognition of degenerative lesions, and may help to distinguish between cerebellar degeneration and neoplasm.

The illustrations are numerous and beautifully reproduced, and line drawings are used with advantage to interpret the skiagrams.

### OCCUPATIONAL THERAPY

*Principles and Practice of Rehabilitation.* By John Elsie Davis, M.A., Sc.D. (Pp. 211. 53.00.) New York: A. S. Barnes and Co., Inc.

This book is mainly concerned with methods of rehabilitation that have been found useful for the mentally ill. The term "rehabilitation" as used by the author is practically synonymous with the older term "occupational therapy." The emphasis is on the scientific approach; each individual has to be assessed for his assets as well as his liabilities before a plan of rehabilitation is drawn up. Attention is paid first to the individual's peculiarities and then to the problem of his socialization. The author points out the importance of the gap that is apt to exist between the kind of activities available in hospital and the kind of work that the patient will be expected to face when he has to re-establish himself as a wage-earning unit in the world outside. In the treatment itself the author reminds us that we have on the one hand to be content to begin with very simple activities to suit the patient's level of performance; but that, on the other hand, his self-esteem must not be hurt by introducing him to a childish type of occupation.

The book contains a discussion of principles and seems to come down on the side of work as an end in itself. Galer is quoted to the effect that work is Nature's best physician. Nevertheless the author does not fail to emphasize as well what work means in terms of self-esteem. Examples from the experience of countries at war are added as illustrations, and the point is made that a better community organization, in peacetime might maintain as useful members of the community many individuals who ordinarily become chronic neurotics, or at least a burden to themselves or others.

### CLINICAL PATHOLOGY

*Clinical Laboratory Diagnosis.* By Samuel A. Levinson, M.S., M.D., and Robert P. MacFate, M.S., Ph.D. Second edition, thoroughly revised. (Pp. 950; illustrated 48s.) London: Henry Kimpton, 1943.

It is doubtful whether anyone can be an authority on all branches of clinical pathology, and somewhat doubtful whether a single book can properly cover the whole subject: individual works on bacteriology, haematology, pathological chemistry, histology, and toxicology are likely to be better sources of information. There are nevertheless several American omnibus

extbooks which attempt to cover the whole field of laboratory work in relation to medicine, and among the more comprehensive is Levinson and MacFate's *Clinical Laboratory Diagnosis*. In the second edition of this work one unusual feature in the original volume has been omitted: this was a full set of instructions for conducting a practical course in the subject for students. Much has happened during the past six years, and additions consequently more than balance this loss: these include a description of photometric methods for chemical estimation, a discussion of acid-base balance, the study of marrow films, and the new complexities of blood grouping, as well as various new chemical estimations. The redundant and misleading list of "Common Infectious Diseases and the Causative Organisms" which we criticized in the first edition has been omitted; the table of characters of individual bacteria has been expanded to 30 pages, and includes many non-pathogenic species. In a work of such immense scope it is useless to expect that every section shall be faultless or complete; on the other hand, most clinical pathologists if they delve in it long enough will probably find something new and useful.

### STINGING FISHES

*Sting-fish and Seafarer*. By H. Muir Evans. With drawings by Irene Hawkins. (Pp. 180; illustrated. 15s.) London: Faber and Faber.

If you are curious about fishes which sting, and if you are curious about a fellow general practitioner who finds time to become an authority on a branch of natural history, you should read this book. It is attractively printed, clearly illustrated, and not very long, so that no one can have the excuse that it is too large a work for a busy man. In these days when the pursuit of science is regarded as a whole-time job it is pleasant to find a scientist of the old school, an amateur in the true sense of the word, who succeeds in finding much that is both interesting and new. For example, in the fish-market in Madeira "picture to yourself a long snaky-looking animal, as jet black as black patent-leather, of the shape of a flat inner tube of a motor tyre, ending with the head of the greyhound form, with wide gape and monstrous long teeth, and enormous eyes, and the tiny bifurcate fin attached to the tapering tail . . . in addition it carried a curious dagger-like spine behind the vent. Cesar de Noronha published a monograph in Portuguese (1925) on the black scabbard fish, which is little known, and this is what he says: 'Near the anal orifice is a terrible offensive weapon consisting of a short strong spine.' Thus it scarcely needs saying that Dr. Muir Evans is not only a naturalist but that he knows how to write and how to bring his dragons vividly to the reader's fancy. You can learn too of the white scabbard, "a beautiful glistening white fish . . . clothed with silver tissue." In New Zealand it has the name of the "frost fish," because on cold nights it has been known to swim towards the shore in vast numbers, ere to be heaped up in a ridge of corpses. Dr. Muir Evans leaves this to be an example "of the mass migratory molation that has been described in lemmings and spring-ouck." But if you want to know about the springbuck you must read it in the book!

### Notes on Books

*Same Psychology: A Biological Introduction to Psychology*, by Prof. R. J. S. McDOWALL (John Murray; 9s.), is really the second edition of *A Biological Introduction to Psychology* enlarged and rearranged. Like its predecessor it seeks to introduce the student to psychology from a basis of elementary biology. This means that the psychology must be very elementary also. Provided that the book is regarded strictly as an introduction it will serve its purpose, but the trouble is that so many superficial students never get beyond such an introduction and think that when they have read such a book they know all that is necessary to set up as a practical psychotherapist. Looked at from this point of view, which is admittedly unfair, it becomes obvious that the author has had little or no experience of treating the individual patient. The chief additions are the chapters on the effect of mind on body, in which the author fails to make a clear distinction between a conversion symptom and the emotionally induced disturbances of the autonomic nervous system, and the effect of body on mind, in which the "organic" psychoses and fatigue syndromes are briefly referred to. The descriptions of the various schools of psychology are so brief as to be almost ludicrously

inadequate, and the appendix of case histories drawn from the writings of others certainly does not carry the conviction which would be felt if the cases were drawn from the author's own experience.

The Child Health Planning Group (hon. secretary, Dr. J. D. Kershaw, Public Health Department, Town Hall, Accrington, Lancs) has issued a pamphlet, *Education and Health*, dealing with various aspects of the health and well-being of the child and the adolescent, with special reference to school environment and the general system of education. The price of a single copy is 3d., post free.

## Preparations and Appliances

### THE KING'S COLLEGE HOSPITAL ENDOTRACHEAL HARNESS

Dr. A. H. GALLEY, of King's College Hospital, writes:

Your recent account of the Hudson endotracheal harness prompts me to describe a similar device which has the advantage of being home-made. It consists of 19 in. of garter elastic, preferably white, and from  $\frac{1}{4}$  in. to 1 in. in diameter. As will readily be seen from the accompanying diagrams, one end has a loop of tape (A) sewed on, sufficient in length to slip over any of the buttons to be described later. Near the other end four rubber- or linen-covered buttons are attached (B) in line, along the axis of the harness and about  $\frac{1}{4}$  in. apart. Buttons  $\frac{1}{2}$  in. to  $\frac{3}{4}$  in. in diameter are the most suitable. About 6 in. from the button end a length of tape (10 in. is ample) is sewn on to the elastic band so as to leave two free ends of equal length (C). The elastic should be hemmed at both ends to prevent fraying.

When in use the harness is placed around the head in such a position that the attachment of the tape (C) is in the centre of the forehead and the two free ends are tied in a bow around the rubber extension of the endotracheal tube. The loop (A) is then slipped over an appropriate button, leaving the band in slight tension and the rubber extension tube fixed firmly in place. Untying the bow and loosening the loop frees the harness in a matter of moments.

This harness first came into use at King's some ten or eleven years ago, when I was resident anaesthetist, and so far as I am aware no single person claims to have invented it. Like Topsy, "it just grewed." The only part I had in its evolution was to increase the number of buttons from one to four and to suggest the use of rubber buttons. Despite this, it is known in certain irreverent quarters as "Galley's garter"!

No doubt such a simple and obvious piece of apparatus must have been thought out and employed in other institutions, but so far I have never seen it described in any medical publication.

### AN AMPOULE INJECTOR

Burroughs Wellcome and Co. have developed a unit injection device, the "monoject" brand ampoule syringe, to meet the needs of the Forces in the field. It presents a single parenteral dose of sterile solution of morphine or other drug, sealed in a collapsible tube with a welded closure and a sterile hypodermic needle mounted in the nozzle. The needle is protected from damage and contamination by a plastic cap which is threaded and sealed on to the nozzle of the tube. Removal of the cap and piercing the internal seal with the pin provided renders the ampoule syringe ready for immediate use. The manufacturers state that their entire output of "monoject" brand products is at present reserved for the armed Forces; they hope to be able to meet civilian requirements in the near future.

## BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 5 1944

EFFECT OF ANAESTHETICS ON GASTRIC  
TONE AND MOTILITY

In the serious, though comparatively rare, condition of acute dilatation of the stomach gas and large quantities of fluid may accumulate within it. The accumulation of fluid means corresponding losses from other parts of the body, and losses of sodium and chloride: also alkalosis, and possibly tetany. Unless the fluid and electrolyte balances are soon restored death ensues. It appears from the work of Dragstedt and others<sup>1,2</sup> that once the stomach has lost its tone its own secretions stagnate there, as it cannot pass them on to the absorbing part of the gastrointestinal tract lower down. The secretions are lost by regurgitation through the oesophagus, or else they accumulate in the stomach, causing distension, which may be further increased by regurgitation of fluid from the duodenum. In the later stages the distension may act as a stimulus to increased secretion by the stomach, and the pressure of the enlarged stomach may obstruct the lower part of the duodenum. Acute distension of the stomach has been observed in association with several conditions—e.g., in severe diabetes, after an attack of migraine, in the course of pulmonary tuberculosis, or post-operatively; most often, it is claimed, after laparotomy under general anaesthesia. It seems probable, therefore, that acute distension may result from several different causal factors operating together or singly, and among these anaesthesia and various operative procedures are of special interest.

In order the better to assess the role of anaesthesia Johnson and Mann<sup>3</sup> have recently investigated in dogs the effects of different agents and depths of anaesthesia upon gastric tonus and movements. They used animals in each of which a permanent gastric fistula of the Mann-Bollmann type had been made several weeks previously. Through the fistula a balloon was inserted and connected to a recording manometer. For these experiments the animals were in a fasting condition, and observations were made for a control period of 15 to 30 minutes each time before the induction of anaesthesia. The following different agents or combinations of agents were used in different experiments: ether, nitrous oxide and oxygen, nitrous oxide and oxygen with ether, ethylene and oxygen, ether supplementing basal anaesthesia with bromethol (avertin), cyclopropane and oxygen, cyclopropane and oxygen supplementing basal anaesthesia with bromethol, intravenous pentothal sodium. The depth of the anaesthesia was found to be the most important factor: the deeper the anaesthesia, the greater the reduction of gastric tone and motility. Generally, anaesthesia carried to plane 2, stage III, according to

Guedel's criteria,<sup>4</sup> resulted in much-reduced gastric tone and disappearance of motility. Of course, some anaesthetic agents—e.g., nitrous oxide or ethylene—cannot give an anaesthesia of the depth specified. To reach that depth the action of these agents was, in some experiments, reinforced by producing a certain degree of anoxia. The effects on gastric tone and motility were the same as when more potent agents were used without the aid of anoxia. Apparently the effects of anoxia and of anaesthetics upon the stomach are additive.

Johnson and Mann also studied the return of gastric tone and motility after anaesthesia, and the influence of duration of anaesthesia upon the restoration of these. Usually, tone came back before motility, or else they reappeared together. The time required varied widely in individual animals. After ether anaesthesia it was usually 2 to 3 hours, but extremes of 1½ and of 10 hours were observed. In some dogs tone and motility were resumed more rapidly than in others, no matter what anaesthetics were employed. On the whole the times needed for restoration were not very different after the different agents or combinations of agents. A few experiments were made on the effects of lengthy ether anaesthesia. The times needed for restoration of tone and motility were found to be prolonged little, if at all. This is in agreement with Cannon and Murphy's<sup>5,6</sup> finding that in cats ether anaesthesia of long duration prolonged the gastric emptying time little more than ether anaesthesia of short duration. Premedication with atropine and morphine to a degree of drowsiness judged to be comparable with that often produced in man, however, nearly doubled the time needed for the restoration of tone and motility after ether anaesthesia. Johnson and Mann found that after bilateral splanchnicectomy or double vagotomy, or after both operations, the changes brought about in gastric tone and motility during anaesthesia by various agents and during recovery were the same as before those operations. It seems, therefore, that the actions of the agents studied are mainly upon the peripheral motor system of the stomach, with its local neural and muscular components, and that reflex effects through the extrinsic nerves are small.

What remains to be seen is how far the foregoing results hold good for man. Assuming that they do, then it follows that morphine is by no means the ideal agent for pre- and post-operative medication. A substitute for morphine which has its sedative and analgesic actions but not its actions upon the gastro-intestinal tract and respiration is as desirable as it ever was; likewise, a substitute for atropine which inhibits gastro-intestinal activity less. The varying effects of different anaesthetics upon gastric motility and tone are apparently small in comparison with differences between the effects of light anaesthesia and of fairly deep anaesthesia. Depression of gastric tone and motility is more probable after fairly deep anaesthesia, as in abdominal surgery, than after light anaesthesia. How far can such depression resulting from fairly deep anaesthesia be avoided or reduced? A heavy-handed surgeon is likely to require a deeper anaesthesia than his gentler colleague, inasmuch as he is likely to evoke any stretch reflexes which

<sup>1</sup> *Surg. Gynec. Obstet.*, 1931, 52, 1075.<sup>2</sup> Dragstedt, L. R., in Lewis, Dean, *Practice of Surgery*, 6, chap. 10, pp. 1-15.<sup>3</sup> W. F. Prior Company, Hagerstown, Md. 1940.<sup>4</sup> *Surgery*, 1942, 12, 599.<sup>5</sup> Guedel, A. E., *Inhalation Anaesthesia*, p. 14. Macmillan, New York. 1937.<sup>6</sup> *Ann. Surg.*, 1906, 43, 512.<sup>7</sup> *J. Amer. med. Ass.*, 1907, 49, 840.

remain and so hinder his own work. But whether or not this happens, the anaesthetist's aim must be to provide the surgeon with adequate muscular relaxation for the operation intended, and at the same time not to depress the patient by deeper and lengthier anaesthesia than is necessary. In pursuit of these aims the skilled anaesthetist can anticipate the surgeon's needs and accordingly shorten the periods of deeper anaesthesia. This is not, however, the only method available to the anaesthetist; among others are spinal anaesthesia and the combination of peripheral nerve block with light general anaesthesia. In their experiments on dogs Johnson and Mann found that even when spinal anaesthesia extended to the upper thoracic or the lower cervical region gastric tone and motility were depressed. This forms an interesting contrast with the well-known effect of spinal anaesthesia in causing increased activity of the small intestine—an observation, moreover, which according to the authors is not accounted for by reflex stimulation of the splanchnic nerves, as it could be repeated after previous splanchnicectomy, and which also is not accounted for by any action of their local anaesthetic (procaine hydrochloride) mediated through the blood stream, because the injection of quite large amounts of procaine near the spinal cord did not influence gastric tone and motility. Johnson and Mann did not investigate the second of the alternative methods mentioned earlier—the combination of nerve block with light general anaesthesia. But it may have advantages over general anaesthesia, particularly for abdominal surgery, not only in depressing gastric tone and motility less but also in depressing reflex activity in other parts of the body less—e.g., the regulation of blood pressure. It would seem that when procaine is injected near the spine the effects of this via the blood stream upon gastric tone and motility are small, and that the second alternative method is well worth further investigation.

Beyond those considerations, which are connected with the anaesthetic and its administration, there are others certainly not less important. For example, nothing in Johnson and Mann's work diminishes the significance of Cannon and Murphy's<sup>3</sup> x-ray studies of the emptying of the cat's stomach. They found that, whilst ether anaesthesia and laparotomy delayed the emptying somewhat, these effects were small in comparison with those of handling the digestive organs. Even quite gentle handling delayed the emptying considerably. In this connexion their observation that handling of the small intestine inhibited gastric activity is another which cannot be accounted for by reflex stimulation of the splanchnic nerves, as the inhibition occurred equally after splanchnicectomy (Cannon and Murphy<sup>3</sup>).

While Johnson and Mann's work makes clearer the influence of some of the factors concerned in acute gastric dilatation, nevertheless more knowledge of the effects of various operative procedures is needed. The treatment of acute dilatation, once the condition arises, remains symptomatic—namely, aspiration of the collected gas and fluid in the stomach (Paine and Wangenstein<sup>4</sup>), together with replacement of the lost fluid and electrolytes, usually by the intravenous route.

## SKIN DISINFECTION

Much the commonest clinical use for disinfectants is for the sterilization of the skin, yet there is still remarkable difference of opinion about the merits of various agents for this purpose. Some explanation for this is to be found in the great diversity of methods employed for testing them: treated skin has been swabbed, scraped, or actually excised, and cultivated in various ways with or without attention to the pitfalls which beset sterility tests of material still containing disinfectant. The very elaborate method recently evolved by Price has been used with minor modifications by C. A. Hatfield and J. S. Lockwood.<sup>1</sup> This consists first of ten successive scrubblings of the hands each with a fresh sterile brush and a weighed amount of soap powder, following an exact ritual and timed with a stop watch to last 1 minute, the lather being then washed off with 1 litre of sterile water into a sterile basin. The disinfectant is then applied, and after its action five more identical scrubblings and rinses are carried out. Pour plates are then made with a measured inoculum from each of the 15 basins, and colonies counted. The count per c.c.m. of rinse water falls, steeply at first, from an initial 10,000 or so to about 600, and there remains: in other words further scrubblings continue to remove about the same number of bacteria. Intervening treatment of the skin by an efficient disinfectant permanently depresses the counts, and the last five are then on a much lower level. Tests by this laborious method award first prize to tincture of iodine followed by alcohol, and second to alcohol alone. There is no reason for doubting the significance of these findings, and those who like to conclude from them that old-fashioned remedies are best may do so; but let it be observed that iodine and spirit are both in very short supply in this country at present; we are in fact asked not to use either when anything else will serve. It should also be pointed out that a good disinfectant for normal skin may be a very bad one for a wound, and that whatever spirit may do to skin—and this, by the way, is not to sterilize it completely—it should certainly not be relied on for sterilizing instruments. Various unnamed mercurial "tinctures" whose identity can be guessed gave poor results, and so did a synthetic detergent; but the test was scarcely fair to this, because substances of this class are neutralized by soaps.

Among other recent experimenters in this field F. Neufeld and O. Schütz<sup>2</sup> also commend alcohol, but for different reasons. Advocates of the synthetic detergent are many. J. Frankl<sup>3</sup> and E. Gottsacker<sup>4</sup> extol the virtue of "zephyrol," which, it should be remembered, was first introduced by no less an authority than Domagk. Each of these authors stresses the persistence of its action: sweat inside a surgical glove is sterile after two hours' wear if the hand has previously been disinfected with zephyrol. If this is really so it should be the answer to staphylococcal infection of clean operation wounds caused by minute perforations of the surgeon's gloves. Zephyrol (in the U.S.A. "zephyran") has not been seen much in this

<sup>1</sup> *Surgery*, 1943, 13, 931.

<sup>4</sup> *Arch. Hyg. Bakt.*, 1942, 123, 11.

country, but we now have our own disinfectant of this type in CTAB—cetyltrimethyl ammonium bromide—first favourably reported on by J. M. Barnes.<sup>5</sup> For the disinfection of normal skin, the preliminary cleansing of superficial wounds and burns, and the disinfection of baths, bowls, and certain instruments, such compounds have qualities that should strongly commend them.

Two other ingenious methods of testing a skin disinfectant have been advocated. H. Habs and K. H. Kirschner<sup>6</sup> heavily contaminate shaven guinea-pigs' skin with *Ps. pyocyanea*, treat it with disinfectant, and cultivate multiple excised fragments of skin in broth containing malachite green; this inhibits the growth of skin bacteria but not that of *Ps. pyocyanea*, and thus gives a clear-cut result. W. J. Nungester and Alice H. Kempf<sup>7</sup> go perhaps one better by infecting a mouse's tail with virulent pyogenic cocci, and after disinfectant treatment cut off half an inch and place it in the peritoneal cavity: this test—evidence of bacterial survival being a fatal peritonitis—more often gave a positive result than simple cultivation. The time will perhaps never come when this welter of miscellaneous methods is replaced by a single universally recognized technique for testing skin disinfectants. Medical literature would lose some of its novelty if this were to happen, but the unfortunate user would be able to formulate clearer ideas.

## DOCTOR AND PATIENT

It is a common complaint against the hospitals that patients are not told enough about their illnesses and that there is almost a conspiracy on the part of doctors and hospital authorities. What the psychologist calls "channels of communication" become increasingly important and at the same time harder to keep open as an organization grows in size and complexity. In fact communications can be maintained only by persistent and conscious endeavour. A patient attends a hospital for treatment of an inguinal hernia and is found, to his misfortune, to have some lesion of which he was wholly unaware, such as coarctation of the aorta or an early Paget's disease. Before he knows where he is, he is an inmate of a medical ward and is submitted to investigations that have no obvious relevance to his complaint. Finally he is discharged, still with his hernia and naturally disgruntled. Students and housemen need a frequent reminder that they should on no account let a patient out of hospital without making sure that they know what he actually came in for and whether he is satisfied. They should also realize that—with the growth of contributory schemes and payments for services rendered on the one hand, and, on the other, the subvention of medical education by Government grants, research funds, and hospital facilities—it is more appropriate to look upon the medical student as the recipient of charity than the patient. Most consultants would confess that they learn more from their private patients than from their hospital patients. This is often put down to the superior intelligence of the former. Nevertheless, other factors such as expenditure of time and psychological attitude are different, and the student should be taught that the nearer he can get to the private-patient relationship in studying his hospital patients the more he will learn about his art. It

is unfortunate that so many medical students have to be trained in large cities such as London, where teaching hospitals have less local responsibility than in smaller cities and where the spirit of an old-established charity still haunts the wards. They get a better discipline in the relationship of hospital, doctor, and patient if they work in a small provincial centre—particularly if they regard the local weekly paper as one of their most important texts. What happens in the hospital is not merely news: it is a major interest of the community. In such a centre the student will learn most rapidly the unwisdom of operating on advanced malignant disease or of carrying out risky diagnostic procedures unless he has made certain that the patient and the relatives fully realize and accept the position. It is easy to be thoughtless of the individual when medicine is organized on the lines of quantity production, as it is in large hospitals and in industrial establishments. And care must be taken that no bafflement or disillusion of the individual taints the health centres and unit hospitals which make such a brave showing in pictures of the future.

The industrial medical officer obviously runs the risk of working across the grain rather than with it in his dealings with the worker. He is peculiarly liable to be 'affiliated with "they" and "them," those paranoid fantasies, on which we all vent our spleen—and will continue to do so whatever "ism" we live under. Just as the primary interest of the hospital doctor is diagnosis, so the primary interest of the factory doctor is maintenance of a low sickness rate. In the one case patients tend to become "clinical material," in the other they become "labour," unless we are always mindful of our professional failings. Yet the industrial medical officer is often justified in his complaints against the private practitioner. One of the main purposes of doctors is to keep people at work, both for their patients' sake and for the sake of the country. It is very wrong, therefore, for a private practitioner to attribute banal symptoms to industrial processes of which he knows nothing, to give long holidays for trivial maladies, or to declare a worker unfit for a particular job on eleemosynary rather than scientific grounds.<sup>1</sup> Medicine has a duty to both the individual and the community, and, whatever state of society we live under, we can never be absolved from the task of bringing harmony between them.

## VASCULAR SUPPLY OF NERVES

Hitherto more attention seems to have been bestowed on the nerve supply of vessels than on the vascular supply of nerves. The importance of the latter was, however, fully appreciated by some of the earlier anatomists and physiologists, and W. E. Adams of Leeds has done valuable service in presenting a historical review of the subject in which he discusses the anatomical and physiological findings of early and recent research workers.<sup>2</sup> These provide an explanation for many of the procedures which have been adopted during the last 50 years by such practical nerve specialists as Weir Mitchell, Victor Horsley, René Leriche, François Frank, Harvey Cushing, and others. The anatomical evidence includes observations on the vascular supply of: (1) peripheral nerves; (2) the spinal and cranial ganglia and their roots; (3) the sympathetic nervous system; (4) vascular plexuses around cell centres and nerves in embryos; (5) intraneural plexuses; (6) the innervation by non-medullated nerves of the tunica media of nutrient arteries running in the epi- and peri-neurium, and the termination of some non-medullated fibres in end-

<sup>5</sup> *Lancet*, 1942, i, 531.

<sup>6</sup> *Z. Hyg. u. Bakt.*, 1942, 124, 557.

<sup>7</sup> *J. Infect. Dis.*, 1942, 71, 174.

<sup>1</sup> Babey, A. M., *J. Amer. med. Ass.*, 1943, 112, 395.  
*J. Anat.*, 1942, 76, 323.

bulbs indicating an afferent sensory function for these fibres, the "nervi nervorum" thus being both efferent and afferent—the efferent fibres controlling the calibre of the vessels supplying the nerve and the afferent fibres conveying sensory impulses; and lastly the veins of nerves, which have been specially investigated by Quénu and Lélars.<sup>2</sup> Anatomically the nutrient arteries of the nerves are not end-arteries, there being a continuous longitudinal anastomosis within each nerve. Tonkow also distinguishes between "arteriae nutritiae" and "arteriae comites," though the latter, which may run in or on the nerve, sometimes give off arteriae nutritiae. From the practical standpoint a knowledge of the intrinsic vascular supply of nerves is valuable in relation not only to the regeneration of peripheral nerves but also to the severe symptoms which may follow ischaemia of nerves. Of practical significance, too, is the recognition that the intrinsic arteries of peripheral nerves are separately supplied by prolongations of the sympathetic system and are subject to changes in that system. These changes appear often to underlie such conditions as causalgia, post-traumatic spreading neuralgias, vasoconstrictor and vasodilator disturbances such as Raynaud's disease, angioneurotic oedema, angina pectoris, and some obliterative affections of the arteries and veins. Mayer found that if the facial nerve of the rabbit is devascularized *in situ* it loses its excitability in 15 to 30 minutes. Fröhlich and Tait obtained similar results with the sciatic nerve of the rabbit. Okada produced degeneration of the sciatic nerve of the rabbit simply by dividing the inferior gluteal artery. This experiment, as Adams points out, is significant because it shows that the occlusion of a single regional vessel may exert a profound effect on the nerve which it supplies, and also that this type of degeneration—"ischaemic"—differs from Wallerian degeneration in that there is no actual interruption in the continuity of the axis cylinder. It has also been demonstrated that ischaemia need not be complete before it affects the transmission of both motor and sensory impulses. Moreover, Lewis and others have shown, by the use of a clamp, that revascularization following a localized ischaemia produced by temporary pressure on a nerve is attended by recovery from paralysis and changes in the nerve which are interpreted as the subjective sensation of tingling. Clinical evidence, as well as that furnished by operation on the human subject, thus appears to be substantiated by the anatomical-physiological observations collated by Adams. Further, the curative or alleviating effects claimed for such operations as division of the sensory root of the trigeminal nerve and excision of the stellate ganglion or its infiltration with novocain in the treatment of angina pectoris have their justification.

### THE SENILE PUPIL

Rigidity and contraction of the pupil in the aged has a practical significance when dilatation is needed for therapeutic or diagnostic purposes. That the underlying pathological state is sclerosis of the iris vessels is suggested by the occurrence of miotic and sluggish pupils in patients suffering from hypertensive diseases. Larsson and Österlind<sup>4</sup> examined the eyes of fourteen persons aged between 69 and 85 years, and their material formed a continuous series of irides with different powers of pupil dilatation, from absolute immobility to good function. Clinically the changes were depigmentation of the free pupil margin; in advanced cases this goes on to the formation of a structureless, greyish-white, homogeneous membrane. But

these changes in themselves are not definitely related to the changes in power to dilate. Histologically sclerosis of the iris vessels was an outstanding feature, and seemed directly proportionate to the degree of pupil immobility. Hyaline degeneration of the free pupillary border and of the connective-tissue layer between the sphincter and the pigment epithelium was present in the more severe cases. Clearly related to pupil immobility were degenerative changes in the sphincter and dilator fibres of the iris musculature. The authors hold that senile miosis is primarily the result of arteriosclerosis; subsequent degeneration of the iris musculature and hyaline changes intensify the condition. Each one of these affections will make normal dilatation more difficult but not impossible. In combination they result in complete immobility of the pupil.

### TRAINING OF THE ANTHROPOLOGIST

The study of man as a social being has an obvious bearing on the work of reconstruction. Anthropological teaching and research have never yet perhaps received the serious attention which their importance demands. This was largely the theme of Prof. F. C. Bartlett's recent Huxley Memorial Lecture delivered before the Royal Anthropological Institute. So far as university teaching is concerned the Cambridge Professor of Experimental Psychology holds that the training for anthropology should be postgraduate. Human sciences—and anthropology most of all—demand a maturity of outlook and a certain compendious knowledge which can hardly be expected of very young students. In his view the particular school of graduation does not matter very much; in some cases it may well be the school of human experience itself. But he thinks that a special welcome should be accorded to the very best graduate material that the biological and physical sciences can produce, and that efforts to interest this material should be made. Anthropology should seek active working relationships with nearly every other department in the university. It should itself constitute a prolonged experiment in culture contact. Prof. Bartlett went on to indicate three developments which he thinks of vital importance to anthropology. The first is the study of scientific methodology, as important to anthropology as it is to medicine, and for very nearly the same reasons. In both these fields conclusions and decisions have to be made on the basis of behaviour signs which require great skill and insight for their interpretation, and these signs must be interpreted on a basis of scientifically attested knowledge which is constantly and rapidly extending. The second is the manifold use of experiment. Prof. Bartlett wants every anthropological department to have an attached laboratory, or at least to be in very close working relation with suitable laboratories in other departments, so that the student may learn by practice the experimental basis of evidence, the controls necessary and possible in the comparative study of smallish groups, and whatever equipment of tests is likely to help him along his special line of interests. Finally, he said that everybody who is going to be an anthropologist should be encouraged to learn the value, the power, and the limitations of the tools which the statistician can place in his hands. The lecture was a plea for much more thorough organization and research as the basis of anthropological training.

We much regret to announce the death in retirement at Lossiemouth of Dr. John S. Fairbairn, consulting obstetric physician and gynaecologist to St. Thomas's Hospital, formerly Chairman of the Central Midwives Board for England and Wales and President of the Royal College of Obstetricians and Gynaecologists.

## REVACCINATION OF AN ARMY UNIT

BY

P. N. COLEMAN, M.B., Ch.B.

Captain, R.A.M.C.

In the description of vaccination in most standard textbooks of medicine little is said of the reaction to be expected on revaccination. It is very important, however, to distinguish the case in which a revaccination has "taken" with a minimum of reaction because of previous immunity from the case in which it has failed because of faulty technique. In a recent pamphlet issued by the Medical Directorate, G.H.Q., India (1942), this matter was emphasized, and it was pointed out that it is very rare even in the revaccination of persons successfully vaccinated several times previously for a reaction to fail to appear. The reaction is, however, evanescent, and might be missed if inspection of the vaccinated area is delayed until the sixth day. The pamphlet describes two types of reaction to be observed in the revaccination of previously immune persons: the "accelerated" reaction, in which a papule appears after about 36 hours, is maximum on the fourth day, and is subsiding on the sixth day; and the "immediate" reaction, in which the papule appears after 24 hours and is maximum in 48 hours. The following account of a case of smallpox which occurred in a British Army unit shortly after arrival in India, and of the subsequent revaccination of the whole unit, illustrates the points made in this pamphlet, and may therefore be of interest.

## Sequence of Events

On arrival at the port in India the troops were given shore leave, returning to the ship for the night. The next day they disembarked straight into a waiting troop train, in which they remained for the four-day journey to their new station. Twelve days after the shore leave a private soldier complained to his companions that he felt ill. The next morning he reported sick and was admitted to hospital with vomiting, pains in the limbs, and fever. Three days later a definite diagnosis of smallpox was made, and seven days after his admission to hospital he died from haemorrhagic smallpox. There had been no cases of smallpox or chicken-pox on the ship, so it is evident that he contracted the disease during the period of shore leave. He had not been vaccinated in infancy, but his records showed that he was vaccinated in the Army in 1940. No mark of this vaccination could be found.

The soldier was moving freely within the unit for about 18 hours from the time he first felt ill to the time of his removal to hospital. The entire unit of 938 men were regarded as possible contacts; the more probable contacts, however, were the 129 men of the man's own company, who all lived together in one barrack block. Precautions taken were the isolation of the company concerned, disinfection of all fomites, and the revaccination of all contacts. All the men of the company were revaccinated on the day notification of the case of smallpox was received—i.e., four days after the man first complained of feeling ill—and on the following day the rest of the unit were revaccinated. No further cases of smallpox occurred.

## Vaccination State of the Unit on Disembarkation

According to their documents all the men had been vaccinated within the previous five years—47 men in 1939, 713 in 1940, 56 in 1941, and 122 in 1942. They had arrived in the unit from many different parent units over a period of three years; thus their vaccination had been carried out by many different medical officers in many different stations.

## Response observed to Revaccination

As vaccination had been carried out within five years the full classical response to vaccination was not expected to occur in many cases. The arms were therefore inspected at 48 hours, 96 hours, and 6 days after vaccination. The results of a total of 938 vaccinations are given below.

In 656 cases (70%) the sequence of events was as follows: After 48 hours there was already quite a definite reaction. The region of the insertion showed a slight yellow exudate, surrounded by a red area about a quarter of an inch across. In 96 hours the red area was well marked, with a dried yellow exudate over the insertion but no true vesiculation. On the sixth day the reaction was fading rapidly, and in many cases all that then remained was a small dried-up exudate over the insertion. This is the "immediate" reaction described in the pamphlet. In a further 204 cases (22%) no definite reaction was observed after 48 hours, but the reaction had become quite definite after 96 hours, and was of the type described above.

It was fading rapidly by the sixth day, and never showed the classical response. This is the "accelerated" reaction described in the pamphlet. In 31 cases (3%) there was never at any time a very definite response, though even in these cases an area of erythema was observed after either 48 or 96 hours. These cases were regarded as giving a doubtful response, and vaccination was repeated.

Finally, inspection on the sixth day showed that 47 cases (5%) went on to the full classical response to vaccination. These had well-marked vesiculation going on to pustulation, a wider area of surrounding erythema, and axillary adenitis. Of these cases 18 developed a mild fever and had to be excused duty for a few days, though in no instance did any serious symptoms occur. The time taken for the classical response to develop was interesting. On examination after 48 hours, out of 47 cases which later gave the classical response only 11 (23%) were showing the signs of reaction, whereas out of 860 cases which gave the modified reaction 656 (76%) were already showing signs of reaction. Thus the modified response develops more rapidly and fades more rapidly than the classical response.

## Discussion

The value of vaccination in protecting a community from smallpox was once again demonstrated. The occurrence of a fatal case in a man apparently vaccinated three years before was unexpected and disappointing; on the other hand, the man was walking about freely among his companions, in the close conditions that barrack life entails, for 18 hours during the prodromal stage of virulent smallpox, yet no further cases occurred.

The number of completely negative responses to revaccination in a community previously vaccinated within five years was found to be small (3%). But in order to observe this it was necessary to inspect arms at 48 hours and 96 hours after vaccination as well as after 6 days. It is safer, therefore, to regard non-appearance of reaction as evidence of faulty technique, and to repeat vaccination, than to regard it as evidence of a solid immunity. Even after a large number of vaccinations the number of such repetitions will be small.

The proportion of cases which showed the classical response (5%) seemed surprisingly high. Presumably this meant that these cases were relatively non-immune. To what extent this was due to an abnormal rapid fall of immunity since the previous vaccination or to a faulty technique at this vaccination it is difficult to say. It suggests that on entry into an area in which smallpox is endemic it might always be advisable to revaccinate, whatever the record of previous vaccinations.

EDWARD TYSON, M.D., F.R.S.: 1650-1705

## A MODEL BIOGRAPHY

Dr. Edward Tyson has had to wait a long time for his biography, but he now has his reward.<sup>1</sup> If it be, as his biographer maintains, that the monograph he presented to the Royal Society of the anatomy of the chimpanzee in the summer of 1688 set a new model for anatomists, then it is only just that the *Life* now written should be a model for all medical biographers in the future. It is a model biography that has come from the pen of Prof. Ashley Montagu, who is anatomist at Hahnemann College, Philadelphia, and has made many contributions to his subject, particularly to the comparative anatomy of man and ape. Ashley Montagu, however, is much more than an anatomist. He is a man of letters, with a vivid pen and a love of books; he has enthusiasm and industry. He has searched the records of the Tysonian period for every scrap of information.

Tyson, who died a bachelor, was born in Bristol, spent ten years at Oxford University, took his M.D. at Cambridge, and came to London to practise medicine in 1677. Two years later he was elected to the Royal Society, in the proceedings of which he took a very active part, his contributions being chiefly medical and anatomical. At the age of thirty-four (1684) Dr. Tyson was appointed to two offices: he became reader in anatomy at Surgeons' Hall and was appointed physician to Bethlehem and to Bridewell

<sup>1</sup> *Edward Tyson, M.D., F.R.S., 1650-1705, and the Rise of Human and Comparative Anatomy in England. A Study in the History of Science.* By M. F. Ashley Montagu. With foreword by George Sarton. (Pp. 488, 546.) Philadelphia: The American Philosophical Society, Independence Square. 1943.

hospitals. His biographer claims for him that he was the first to give systematic courses in anatomy in London, that a modern lecturer could use his syllabus, and that he was the founder of modern comparative anatomy; he also claims that at Bethlehem Hospital Dr. Tyson was the first to use humane methods in the treatment of the insane.

Tyson's first paper, written while he was still at Oxford (1676), was on "The Scent-Bags in Poll-Cats"; years afterwards, when at Surgeons' Hall, he discovered and described the smegma glands of the human foreskin, which are still known as Tyson's glands. "It is a curious reflection," writes his biographer, "not without a certain moral, that in the world of medicine, to which he made so many highly important and original contributions, Tyson should to-day be remembered alone by the least important of his discoveries." Of his numerous contributions to knowledge, Prof. Ashley Montagu places the monograph published in 1699, when Tyson was in his fiftieth year, far above all the others; its full title runs thus: "Orang-Outang, sive Homo Sylvestris: or, The Anatomy of a Pygmy; Compared with that of a Monkey, an Ape, and a Man. To which is added, A Philological Essay, Concerning the Pygmies, the Cynocephali, the Satyrs, and Sphinges of the Ancients. Wherein it will appear that they are all either Apes or Monkeys, and not Men, as formerly pretended." The biographer gives a vivid account of how his attention was drawn to this monograph, and of how he was drawn into writing a Life of its author. In 1923, when Ashley Montagu was a free-lance student in London, and when the reviewer had the pleasure of meeting him frequently in the museum of the Royal College of Surgeons, he (A. M.) came across, in a work written by Dr. Duckworth, now Master of Jesus College, Cambridge, the following passage: "It constitutes a most remarkable anticipation of modern methods of research, and still serves as a model for investigations into the structure of Man and Apes." On reading this passage Ashley Montagu was moved to ask: "What kind of man could this have been who was responsible for so remarkable a work?" He resolved "at some leisureed time to make his more intimate acquaintance." To his surprise he found there was no biography of Tyson, so he "resolved to put Tyson together" for himself. He set to work on Tyson in 1936; thanks to the enlightened liberality of the American Philosophical Society, he was given opportunities of examining with his own eyes all Tysonian material available in the United States, and to visit England, on the eve of war, and examine documents preserved in Bristol, and those to be found in the archives of the Royal Society and in the Royal College of Physicians of London. Out of these gatherings Tyson has been brought back to life.

A. K.

### INFORMATION ABOUT CANCER

Ever since the British Empire Cancer Campaign was founded one of its most important duties has been from time to time to review new suggestions about the cause and treatment of cancer. In the past the conclusions arrived at have not always reached the medical profession. To-day it is more than ever important that medical men should be able to obtain authoritative information on suggested remedies and theories of causation. The Campaign, therefore, will be willing to communicate its opinion on any new form of treatment on which it has information. It will continue to investigate methods of treatment and theories of causation, and is willing to undertake or to promote research into such subjects, provided the following conditions are fulfilled:

1. That in the opinion of the appropriate expert committee of the Campaign such a subject offers any prospect of advancing the solution of the cancer problem.
2. That the fact that a theory or suggested treatment is being investigated by the British Empire Cancer Campaign shall only be disclosed with the consent of the Campaign.
3. That the Campaign reserves to itself the right to publish, in an appropriate manner, the conclusions reached, whether favourable or otherwise.
4. That in the case of theories concerning causation all available information shall be furnished by the advocate of the theory on the scientific basis and the experimental data, which shall be so detailed that exact repetition of the experiments can be carried out by experts in the field of research concerned.
5. That in the case of methods of treatment the precise nature, composition, and method of administration of the suggested remedy shall be disclosed, and that the evidence shall be collected in accordance with the safeguards as to scientific accuracy which experience has shown to be essential—namely: (a) That cases shall be of proved cancer, in so far as proof is practicable, preferably by histological examination. For choice, they should be cases affecting so-called "accessible" organs—e.g., skin, breast, cervix uteri, and mouth. (b) That every case treated shall be recorded whether the result is

favourable or otherwise. (c) That the clinical records, including follow-up, shall be as full as possible.

6. That in the case of a treatment based on experiments the Campaign reserves to itself the right to confirm the results of such experiments before attempting clinical trials of the remedy.

The Campaign will be happy to arrange for medical men to discuss their hypotheses and experiences with appropriate experts in the field concerned. Its address is 11, Grosvenor Crescent, S.W.1.

### DEFERMENT OF RECRUITMENT OF LABORATORY ASSISTANTS

The attention of pathologists is drawn to the fact that, under the special block procedure arranged with the Ministry of Labour by the Medical Research Council, skilled laboratory assistants are granted deferment on the ground that they are indispensable in the particular posts held: deferment therefore automatically ceases if they change their employers (but not if they are merely moved from one post to another within a single service).

If it is desired to appoint a pathological laboratory assistant who has been granted deferment in respect of another post, the prospective employer should ascertain from the Medical Research Council, before the change is made, whether deferment could be continued: if the transfer is thus approved, then the Ministry of Labour will be asked by the Council to take the necessary action. As a general rule a second transfer in respect of the same man cannot be approved within a short period. (Deferred laboratory assistants whose employers are in a position to release them for transfer may be recruited in their occupational capacity if urgent demands from the Services have to be met.)

## Reports of Societies

### A CANADIAN NEUROLOGICAL HOSPITAL CLINICAL EXPERIENCES BY MEMBERS OF THE STAFF

At the meeting of the Section of Neurology of the Royal Society of Medicine on Jan. 6 members of the staff of the Canadian Neurological Hospital in England recounted some of their clinical experiences.

Lieut.-Col. J. C. RICHARDSON explained that the development of the hospital and of the neurological services of the Canadian Army had taken place in response to needs not foreseen when the hospital was first opened in 1940 with 200 beds for the treatment of head injuries. The hospital had expanded steadily, and by July, 1943, reached its present establishment of 600 beds. Of this number 150 were devoted to a plastic surgery unit and 250 to the neuropsychiatric division on which his remarks were based. During the first year most of the consultant and advisory work was done from the hospital itself; afterwards a consultation centre was established in London, and later still a number of specialists, after spending three months in the neurological hospital, were sent to field medical units and general hospitals, and one physician from each general hospital was attached to the division for from one to three months, so that the medical staff was constantly changing.

The vast majority of the patients were Canadian soldiers, but a considerable number were Canadian airmen, and there were a few civilians and British Service cases. Mild or severe mental disorder comprised 70% of the cases, neurological disorder without permanent mental disturbance 19%, and general medical disorders 8%. This analysis was based on discharges rather than on admissions. The largest group (1,625 out of a total of 4,426 cases in the course of three years) comprised psychoneuroses, about half of this number being anxiety states. Cases of psychopathic personality numbered 646, psychosis 507 (chiefly schizophrenia, with 355 cases), and mental defect 304. Of the cases of neurological disease (828) the largest number (275) were cases of epilepsy, and the next most numerous neurosyphilis (117).

### Organization of the Division

The local organization and methods of the hospital unit had developed as seemed to be required by the nature and number of the cases. Until recently the neurosis cases and the organic neurological cases had been mixed together, and although the

cases of psychosis were segregated the organization proved to be unsatisfactory for investigation and disposal; it also hampered treatment and was not wholly satisfactory for teaching. When in 1943 facilities became available the division was reorganized. The seven wards of the division were allotted to three units. The two closed wards for psychotics and psychopaths remained segregated; two wards were allotted to the neurological unit and three to the neurosis unit. This last unit was the most important from the practical military standpoint, from 55 to 60% of the cases being returned to duty. The cases were admitted to the first ward, which was for the clinical and laboratory investigations and the separation of chronic neurotics. They were then transferred to the second ward, which was for treatment, and finally they were sent to the third ward for training or rehabilitation, where they were handled as soldiers rather than as patients. From this they were discharged to duty—to the field or the base—or sent back to Canada. A rotation scheme was devised so far as the staff were concerned, so that the medical officers gained experience of all kinds of cases.

The experience of the hospital was that neurology, psychiatry, and neurosurgery, planned as different components of one broad field of medical practice, offered the advantage of co-operative handling from the point of view of clinical investigation, diagnosis, treatment, and postgraduate training, and helped to break down the artificial barrier between the neurologist and the psychiatrist. Neuropsychiatry had been called upon to play a far larger part in the selection of troops and allocation of personnel, including choice of candidates for commissions, than was originally anticipated, and it seemed likely that the experience of this military neuropsychiatric division would be of lasting value in planning improvements in teaching hospitals and in directing attention to the psychiatric aspects of somatic illness.

Brig. GEORGE RUDDOCH said that this experiment, carried out under Canadian leadership, would have an immense influence on planning in the future. The term which best described the hospital was "common sense." Air Commodore C. P. SYMONDS added some appreciative comments, and said that in the R.A.F. the proportion of organic nervous diseases to the psychoneuroses was about the same as that mentioned by Col. Richardson. Sir HENRY TIDY spoke in praise of the liaison between neurology and psychiatry which existed at this hospital, and added that it would be to the mutual advantage of psychiatry and general medicine if they were as closely in touch. A New Zealand medical officer commented upon the small proportion of cases of migraine (only 26 cases out of the 828 listed as neurological diseases), and also upon the rarity of malingering. Col. Richardson had said that only three patients were classed as malingers, and in one of these the classification proved afterwards to have been mistaken.

The remainder of the meeting was given over to short papers by members of the staff of the hospital. Major W. S. KEITH gave a report of two cases of staphylococcal infection in which the patients suffered a severe paraplegia about six years afterwards owing to spinal extradural scars. Major B. C. EAGLESHAM brought forward a neuroradiological exhibit. Major A. W. STEWART described some contrecoup lesions in relatively severe cranio-cerebral injuries. In each case the local injury was a moderately well demarcated wound.

Major J. A. WALTERS spoke on some aspects of the treatment of Parkinsonism, basing his remarks on a clinical study in the out-patient department of a voluntary hospital in Toronto. The influence of mind over matter was illustrated in these cases, which showed how the total integration of the many elements in the life of the human being must be kept in mind. It was found that the health and vigour of 44 out of the 47 patients were being reduced by circumstances which could be identified from clinical history and examination. Another finding was that the post-encephalitic group lost their personalities to a certain extent, while the paralysis agitans cases preserved theirs to a far greater degree. The Parkinsonian signs and symptoms were observed to vary in some cases with the patient's psychological state, while in others they appeared to be unaffected. Specific psychotherapy was valuable in most cases; simple explanation, encouragement, and reassurance called for the physician who knew what was wrong and could gain the confidence of his patients, and most of these patients could

be managed by the family doctor better than by the hospital or consultant.

An association known as the British Association of Otolaryngologists has been formed. The officers are: President, W. M. Mollison; Vice-President, L. Colledge; Hon. Treasurer, V. E. Negus; Hon. Secretary, F. C. Ormerod. The temporary address of the Association is 22, Upper Wimpole Street, London, W.1. Tel.: Welbeck 4017.

The following officers of the Joint Tuberculosis Council have been elected for 1944: Chairman, Dr. James Watt; Vice-Chairmen, Drs. A. P. Sutherland and N. Tattersall; Honorary Treasurer, Dr. A. P. Foid (in succession to Dr. G. Jessel); Honorary Auditor, Dr. D. P. Sutherland; Honorary Secretary, Dr. Norman J. England (in succession to Dr. J. B. McDougall). The next meeting of the Council will take place in London on Feb. 19.

## Correspondence

### Infant Mortality in Scotland

Str.—The long-awaited report on infant mortality in Scotland is a disappointing document. Throughout its 85 pages there are but few new facts or ideas. And there was so much new material to be considered, such as the whole impact of the war on diet, housing, and employment, and the great number of overseas experiments and ideas which needed to be translated into Scottish terms. Sir John Boyd Orr's committee has missed a great opportunity. The measure of the manner in which the committee has limited its field is contained in the phrase on page 3: "The committee has confined its attention to pre-war conditions, except in the discussion of stillbirths." This is a most extraordinary statement when one considers not only recent advances in the United States, New Zealand, and Australia, but more so when one considers the impact of evacuation, war feeding, the practical temporary abolition of poverty, and the shortage of fuel—all environmental factors of some importance. There is scarcely a phrase in the whole report to indicate that these issues have been considered.

Even in the field that is covered there are some curious statistical errors. On page 8, for example, South Africa is credited with an infant death rate of 58. This figure applies to the white population only, and not to South Africa generally. Again, on page 30 reference is made to Table 20 on the previous page, but table and text by no means agree. The text also goes on to say that statistics relating to the percentage of the insured population unemployed in English cities are not available. My impression is that they are available in the Ministry of Labour Unemployment Index for the years required (1934-9). Another astonishing statement, on page 61, is that "the rich both in England and Scotland have infantile mortality rates approaching the limit of what is attainable with present knowledge of how to control environment." Considering that the English rate for "the rich"—i.e., Class I on page 16—is 33 per 1,000, and the rate for Scotland demonstrably higher, it is obvious that these figures will have to be halved before they approach the Dutch or New Zealand figures for comparable classes. No mention is made in the report of the extremely low infant death rates in Connecticut, Oregon, or even Minnesota.

The bibliography also shows significant gaps. There is no mention of any Dutch publications or of the work of K. D. Blackfan, C. P. Yaglou, or K. McKenzie, whose research work in the United States surely deserves some notice. Again, no mention is made of the *American Journal of Diseases of Children*, or of the Beveridge report, which has a useful commentary on environmental conditions.

These errors and omissions could perhaps have been overlooked if the committee had shown a little initiative, but it is only too apparent that the nutritional blinkers of the chairman have covered the viewpoint of the entire committee. Over a third of the report deals with pre-war nutrition, and some passages, such as Tables 60 and 61, appear to have been dragged in at the last moment without any attempt to analyse them, or to show in what way breeding experiments in rats may help to reduce infant mortality in Scotland.

The committee's main conclusions are that prematurity and "congenital debility" are mainly responsible for the excessive mortality of the first month, and that infectious diseases, which in turn are due to "poverty, faulty feeding, and poor housing," are the main cause of the high death rate between the first and twelfth months. Two-thirds of the stillbirths are due "to poor physique and poor health of mothers." Prematurity is "the most frequent single cause of death in the first month," but there is no mention of the extensive research carried out in this connexion by the Infants Hospital, Boston, Mass., which showed that in temperatures of 77°, and even higher, and with relative humidities of about 65%, the mortality of premature infants was reduced from 29% to 0.7%. The committee recognizes the importance of providing energy for mother and infant by proper diet, but it does not recognize that it is equally important that there should not be undue loss of energy through too cold an environment. At the moment of birth the infant passes from 99° to 50° or even 40° F. The shock of such a change to a grown man is severe enough, but to an infant it may well be the fundamental cause of death through this, that, or the other disease in a few days. For premature and, indeed, most newly born infants better chances of life are created by maintaining a uniform environmental temperature of 72° and even slightly higher.

Regarding environmental conditions generally, there is not a helpful suggestion in the report. Indeed the committee takes the view that "if climate has any important effect on infantile mortality... it is more than offset by other influences." This is an incredible statement when one remembers that the mortality in winter is *twice as high* as that in the summer. Scotland is on the average 5° colder than Southern England, yet, as Sir William Beveridge brought out in his report, the average Scottish household of 3 to 5 persons spends 13% less on coal, gas, or electricity (Table VIII). It is considered heroic and economical to be Spartan in Scotland, which is hard on the pregnant or nursing mother, and doubly hard on the infant. The committee admits (page 63) that clinics are often "ill lighted, badly ventilated, and dingy; insufficiently heated, cramped, and without facilities for lectures and demonstrations." But the report makes no recommendation that would remedy these faults.

It is particularly to be regretted that the committee has not considered in detail the statistics or environmental conditions of 1940-1-2 and even 1943, for in those years there was singularly little unemployment or poverty in Scotland, and diets have been "Wooltonized" to a degree; but the infant death rates are still excessively high, that for 1941 being 83 per 1,000 and that for 1942 69 per 1,000, both of which are higher than the 1939 rate. The English figures for the same two years are 59 and 49, the latter being the lowest on record, in spite of housing difficulties of an unprecedented degree.

The committee has skimmed its job. The Secretary of State for Scotland would do well to appoint a new Commission or committee to consider infant mortality problems in Scotland in an angle other than that of nutrition, and he would do extremely well if he instructed the new committee to consider at first hand recent developments and investigations in the U.S.A., New Zealand, Australia, and even Hertfordshire. —I am, etc.,

S. F. MARKHAM, M.P.

### Sciatica

SIR.—Anyone who reads in succession Mr. Harry Platt's interesting historical survey of the orthopaedic approach to the aetiology and treatment of sciatica, Mr. Ross-Smith's conclusions from an experience of 7,000 cases, and Dr. Cyriax's statement of his views as a pioneer in physiotherapy will find himself in such a fog of fact and fantasy that the need for debunking will appear more necessary than ever. Dr. Cyriax gives a list of the many "common lesions setting up unilateral sciatica," each with its appropriate treatment. Excluding "functional pain," which he cannot seriously regard as a "lesion," they are almost all hypothetical, having no actually observed pathological basis. What is "non-frictional sciatic periradiculitis"? What evidence is there that unilateral sciatic neuritis ever results from "poisoning with a heavy metal or

alcohols"? What is the clinical difference between gluteal myositis and gluteal fibrositis, and is there any evidence that actual inflammation of muscle or fascia exists in these conditions? If it did, would not deep massage be the worst possible treatment?

Mr. Ross-Smith appears to think that I regard sciatica as purely hysterical in origin. I don't. I believe that almost all cases have a physical basis at the onset, though this is often trivial and generally disappears rapidly with treatment by rest alone. There is, however, a great risk that the pain will be perpetuated as a hysterical symptom as a result of associated psychological causes. This can be prevented if treatment by rest is accompanied and followed by simple psychotherapy in the form of explanation, persuasion, and re-education (now commonly called rehabilitation), without resort to suggestion, whether conscious or unconscious, in the form of some kind of "specific" treatment.

It is not surprising that Mr. Ross-Smith has a poor opinion of psychotherapy in view of his belief that the first step in such treatment is to tell the patient that his pain is imaginary. He regards the diagnosis of hysteria as "absurd and unkind," although it entails a certainty of rapid cure. It is of course both absurd and unkind if hysteria is regarded, as Mr. Ross-Smith apparently regards it, as synonymous with malingering. Like Mr. Ross-Smith, I have seen epidural injections of novocain give relief, but whereas he is sure its effect is not psychological, I am equally sure that it is. William Evans, who invented the treatment, found that normal saline solution was as effective as novocain, and I soon found that epidural injection had no advantage over the older treatment by injection in the neighbourhood of the nerve trunk. Such methods of gross suggestion do no harm; but this is not the case with the "elimination of remote focal sepsis," which Mr. Ross-Smith advocates, for the wholesale extraction of septic teeth often does irreparable damage, and there is not the slightest evidence that focal sepsis is ever a factor in the pathogenesis of sciatica. It is astonishing that Mr. Ross-Smith recognizes disk compression as the cause of pain in only 2% of cases, whereas all neurosurgeons and most orthopaedic surgeons and neurologists would put the figure at 20% at least and probably much higher.

Finally I should like to draw attention to the important investigations of Major F. A. Elliott published in the *Lancet* since the appearance of my paper. He has shown that a prolapsed disk may give rise to myalgic areas in muscles supplied by the compressed roots which are indistinguishable from those caused by so-called fibrositis both clinically and in their response to procaine injections. It seems likely, therefore, that some of the cases of sciatica hitherto regarded as of fibrositic origin are really caused by disk pressure. —I am, etc.,

Oxford.

ARTHUR HURST.

P.S.—The above letter was written before the appearance of the *Journal* of Jan. 22, in which Mr. Blundell Bankart gives good reasons for disagreeing with the views on the aetiology of sciatica expressed by Prof. Harry Platt, Mr. Ross-Smith, and Dr. Cyriax, but no good reason for accepting spinal arthritis as the most common cause. Dr. George Macdonald ascribes his successful treatment by manipulation to his superior technique, though I expect it is more the unconscious suggestion which accompanies it than the actual manipulation which is the secret of his success. Dr. C. H. C. Dalton's views on treatment are much the same as mine, except that he treats the hysterical sequel of the primary lesion by short-wave suggestion instead of a more rational, though not necessarily more successful, form of psychotherapy. He wisely emphasizes the fact that the exertion of travelling to the treatment room more than outweighs the beneficial effect of any form of physiotherapy in the acute stage of sciatica.

A. H.

SIR.—From the correspondence on this subject it transpires that many favour the thesis that at least a majority of cases of sciatica originate through some form of oedema or fibrosis around the lumbosacral nerve roots. For several years I have been injecting small doses of local anaesthetic into the foramina, where acute tenderness is produced by deep pressure

in the foramina by means of a probe. A match-stick does excellently, and leaves behind it a small pink spot into which the hypodermic needle is inserted to a distance of one inch or so. Up to 800 cases have been treated thus with really satisfactory results. This treatment is always reinforced by forcible active exercises, thereby avoiding, in nearly every case, passive manipulations. Furthermore, determined patients who persevere with the exercises for the rest of their lives do not suffer from recurrences. My own is a case in point.—I am, etc.,

Reading.

A. H. PRICE.

### Suggestion

SIR.—Thought and belief have much in common, but there is a distinction between them though the words are often used as synonyms. "I think" or "I believe so-and-so" is just a matter of taste in words. There is a close correlation in many ways, but they are not the same. If I believe a thing, I must think it true, but the converse is not necessarily the case. Tertullian declared that he believed because it was impossible. He was speaking with the religious insight vouchsafed only to the ecstatic. Few can travel with him there, but it is not so difficult to have a notion of what he meant. Thought is probably a function of the cerebrum, though where therein, if anywhere, it is localized is a matter of surmise. Belief, in a way not understood, is probably diffused throughout the cells of a living organism. We can hold a belief in our bones.

Suggestion is a matter of belief and not thought. We cannot add to our stature by taking thought, but much can be done by faith. In Biblical times pathology was different from nowadays. Disease was attributed partly to demonic possession. Those able to expel the demon would cure the illness. Three things were necessary: (1) a belief in this view of disease; (2) a belief by the exorciser in his power; and (3) a belief in him by the sufferer. There is no need to consider any miraculous intervention, though this may have been the explanation. Many apparently parallel cases exist. The aboriginal black in Australia attributes disease to the presence of a foreign body within him, not unlike a demon. The all-powerful and much-respected medicine man treats him by means of a ritual dance, appropriate incantations, and the removal of a foreign body—a piece of crystal. He has brought the crystal in the equivalent of his waistcoat pocket. But there is reason to believe that no fraud is practised. The primitive black with his acute powers of perception knows that the crystal has been brought by the medicine man. It is a symbol of the indwelling evil, and this has been extirpated by the appropriate rites. Once again the same three principles are operative. Wides is their application. Suggestion is the name given to the process, but little else that is helpful is forthcoming.

Often almost contemptuous is its dismissal as "only suggestion" by those thinking of the complicated dexterity required by a modern major operation. The apotheosis of the barber has gone too far. Hair-cutting and blood-letting is too limited a field, and there can be no question of the miscellaneous virtues of the modern surgeon, but abetted by the marvels of the anaesthetist he has tried to do too much. Suggestion, so contemptuously dismissed at the front door, has come in through the window. The scene is familiar though the setting is different. The ritual of an operating theatre replaces that of the medicine man. Maybe a gastro-enterostomy is to be performed for a duodenal ulcer without pyloric obstruction. After a tedious convalescence a full recovery is made, and perhaps for many years the patient is free from all symptoms. He is confident that he has been cured. How has this come about? The theory on which the operation is based is completely irrational, but both the surgeon and the patient believe otherwise. This operation has latterly lost much of its popularity, but there are many to compensate for this. A favourite now, to judge from recent correspondence in the *Journal*, is an attack upon the lower vertebral cartilages in cases of sciatica: quite a considerable procedure.

Turning to the physician's side of the healing art, something of the same kind of thing is found. Autohaemotherapy for, say, recurrent urticaria is a good example. A stutter of theory, a grandiloquent name, a remarkable procedure, and the mantle of Aesculapius, perhaps in the shape of a white coat,

are not to be withstood. It can rarely occur to the patient that his doctor does not know what he is doing. The same absence of rationality characterizes another and very modern form of treatment. Shock or convulsive therapy is its name. First used for mental disorders, it is now employed for a variety of nervous illnesses. "Shake the bottle" we stick on to some of our mixtures. At least we know what we are shaking. The exponent of shock treatment makes no such claim. Much electrical equipment is often visible and that may be a clue to its success. Psycho-analysis is another example. From a mass of recondite pornography the valuable conception of the unconscious mind must be separated. Loud are the protests that suggestion plays no part in the curative processes—too loud, I think, and the unwarranted assumption is made that what has been laboriously disinterred from the unconscious will cease to operate adversely when it has become conscious. A long course of treatment is involved, and the surrogate of the medicine man has plenty of scope for his talents, not to mention the time given to the *vis medicatrix naturae*.

All these forms of treatment claim that they cure their patients. Perhaps they do. But others make the same claim, and if one relies on the same kind of evidence they also probably do. The list is a long one. It includes Christian Science, faith healing, chiropraxis, osteopathy, homeopathy, patent medicines, and many others. Their diversity suggests that the factor already considered is operative. If suggestion is so powerful should not an attempt be made to control its protean guises? With so much talk of preventive medicine current it is a melancholy reflection that one cause of death is very rare—so rare in fact that its acceptability to the Registrar-General is doubtful. Yet there is much to be said for it, and it is what we should like all our patients to die from with the "inevitability of gradualness" in the plenitude of their days: death from old age.—I am, etc.,

London, S.W.1.

E. GALLOP.

### War in the Nursery

SIR.—The anonymous article under this title (Jan. 8, p. 50) was a curious one. It seemed designed to make the flesh creep, and caused one to wonder how so many survive this ordeal of battle which is said to attend the beginnings of human existence, and succeed in developing into comparatively normal beings. It may be, however, that there were half-truths, exaggerations, and omissions in the descriptions, whose object apparently was to cast suspicion on the usefulness and desirability of children's nurseries.

Only a vague reference was made to mother-substitutes, who, in the persons of child-nurses and "nannies," have taken a large part of the mother's place in many well-appointed homes. There was a complete omission also to take into account the psychological effect on both mother and child of an overworked and tired-out woman struggling throughout the twenty-four hours with a young family, with no domestic help, and with cooking, washing, etc., to do. It is conceivable that a qualified member of a nursery staff, loving habits and adopting by choice a difficult and not-too-well-remunerated vocation, may make an effective temporary mother-substitute, and be able to win the co-operation of the child in all that concerns its welfare. It is also true, and nurseries are not unhappy places but the reverse, where the conditions are what they can and should be.

We must hope that mothers of young children will not be employed in post-war industry. It is certainly desirable that the mother should have the nurture and welfare of the child in her care. But experience shows that occasional breaks are good for both mother and child, and that they increase rather than decrease the sense of parental responsibility. It is permissible to hope, therefore, that our war nurseries will be transformed into extensions of child welfare service, to be available for a few hours' rest, for cases of illness in the home, a new confinement, or any other domestic disturbance, which at present bring anxiety to the mother and, it may be, unavoidable neglect of the child.

The reflections on the war situation in this article were also surprising. It is a far-fetched assumption that infants are aware of and directly affected by "the destructive impulses let loose in war," and that these "may serve to fan the flame of

aggression natural to the nursery age . . . provoking further fear and reactive resistance to a world so dangerous."

Psychological theorizations must be balanced and be seasoned with common sense and a sense of humour if they are to be helpful to those engaged in public or personal service.—I am, etc.,

London, S.W.1.

T. DRUMMOND SHIELS.

SIR.—Your recent annotation on war in the nursery (Jan. 8, p. 50) makes me wonder if your criticisms are quite fair to the wartime nurseries. I feel that the best type of nursery education is desirable for the great majority of children, and that there is a real danger to the whole nursery movement in substituting the wartime nursery and the nursery class for the fully equipped, properly housed, and adequately staffed nursery school. I wonder if the writer realizes the difficulties that beset the wartime nursery from the outset? Only one fully trained teacher is allowed for a group of nurseries, and the actual work among the children is carried out largely by probationers wholly untrained, or by girls who have taken the Child Care Reserve Course of three weeks' duration, for a trained deputy is not always allowed. Obviously the selection of probationers is of paramount importance, but the Ministry of Labour may not view this in the same light as the teacher. Skilled help is essential if the potential scenes your article so deplores are to be avoided, and the teacher has to train her helpers *pari passu* with their employment in the great majority of cases.

The second great difficulty in the wartime nursery is equipment. Admirable domestic equipment is provided, and the children can be comfortably seated, fed, and rested without difficulty, but these manœuvres occupy only a fraction of the nursery day. A sum of £15 is allowed for the provision of all play material for forty children, and recently a replacement allowance of 2s. 6d. per head has been granted! The teacher has to beg, wangle, or buy her own material if she wants her nursery to have a chance of success. The work of the Fire Service and of other voluntary bodies has been a great help to these nurseries. Is it fair in the midst of all this to compare these nurseries with well-equipped, skilfully staffed nurseries and expect comparable results in every case? A high incidence of unhappiness is never a necessary accompaniment of any nursery that has the children's activities adequately provided for.

The position of the under 5's in the elementary school is often much more unsatisfactory than that of the nursery child. Children may be admitted to these nursery classes from the age of 3 onwards, and often no special nursery technique or material is available for them. The classes are often overcrowded and understaffed, and the harassed teacher may have as many as fifty children without a helper. How can she possibly put any of her nursery principles into practice? She must rely on old formal measures to avoid chaos. Now the teacher is expected to add to her other duties the giving of vitamin supplements and iron tablets, which the children certainly should have.

That there are unsatisfactory nurseries is no doubt true, is it altogether surprising in the face of these difficulties? That there can be successful nurseries is equally true, as I know from my own experience, but in these the children's needs are all catered for, and this means, above all, skilled help.—I am, etc.,

Scarborough.

ELIZABETH R. CAMERON.

#### Effect of Pregnancy and Parturition on Pulmonary Tuberculosis

SIR.—Dr. R. S. McDade's letter (Jan. 15, p. 98) regarding my paper on this subject raises points which I do not think would have arisen had paper restrictions not precluded the publication of the summarized case records that I had prepared, and I am grateful to him for providing this opportunity of elucidating them.

I am not influenced by the fact that my conclusion that "active pulmonary disease is seldom accelerated by pregnancy and labour" conflicts with generally accepted beliefs, but I do wish to convince Dr. McDade (and possibly others) that this conclusion does not conflict with my own results. To this end may I be allowed to supply the following information?

While it is mainly true that only "treatable" cases are admitted to the E.C.C. Hospital, Black Notley, this is a generalization, not a rule, and no selection was exercised in respect of the pregnancy cases. Of the seven "progressive" cases which showed retrogression and to which Dr. McDade refers, three patients were admitted with hopeless extensive and bilateral disease. One other had extensive bronchopneumonic disease for which a pneumothorax was induced early in pregnancy, and a small focus appeared in the opposite lung 4 weeks after labour; 1 year and 9 months after labour both sides were quiescent. The remaining three patients had disease confined to one lung before labour and showed radiological increase after. One of these became quiescent 3 months later. Among the eighteen active cases which did not retrogress, nine had active bilateral disease on admission; seven improved and two were ultimately discharged quiescent. Nine had active unilateral disease; five improved and four were ultimately discharged quiescent.

I must in turn criticize Dr. McDade for citing percentage figures on seven out of twenty-five cases. In my paper I pointed out that 100 cases could only be taken as representative and are not statistically significant; he is not justified in comparing such small numbers of unselected pregnancy cases with the large numbers of "active," largely selected, non-pregnant cases which pass through our sanatorium wards.

Finally, lest he think that I would never advise termination of pregnancy in cases of pulmonary tuberculosis, I refer Dr. McDade to the penultimate sentence of my paper, in which I state that therapeutic abortion should be considered in certain cases of active disease.—I am, etc.,

E.C.C. Hospital, Black Notley.

R. C. COHEN,  
Deputy Medical Superintendent.

#### Cerebral Malaria

SIR.—In the article on cerebral malaria by Surg. Lieut. Sneddon (Dec. 25, p. 814) and in the letters by Major Cameron and Dr. Macleod (Jan. 22, p. 128) I am surprised no mention is made of mepacrine, and only in Dr. Macleod's letter of plasmoquin. I write from the same extensive experience in Assam as Major Cameron had in Malaya, and would commend to those who are meeting malaria without much knowledge of its treatment the article by the late Prof. Warrington Yorke in the *Journal* of July 18, 1942 (p. 61). Personally I would put in importance the treatment with mepacrine before that with quinine; I also use plasmoquin towards the end of treatment because of its value in preventing relapses.—I am, etc.,

Poole.

W. B. MCQUEEN.

#### Treatment of Malaria

SIR.—The article on malaria in British troops in West Africa by Hughes and Bomford (*B.M.J.*, Jan. 15) must be of the greatest interest to all concerned in the treatment of malaria.

From experience in the Far East I found that many physicians did not fully appreciate the importance of keeping patients in hospital, or, in the case of private patients, under conditions approximating hospitalization in their own homes, for a minimum of 14 days. This period was adhered to by me in European, Eurasian, and Chinese patients.

Some Far East colleagues will no doubt remember the severe clinical types of subtertian malaria very prevalent in such areas of Hong Kong Island as Deep Water Bay and Repulse Bay, and in certain areas of the new territories of the mainland. The majority of such, especially in Europeans and Eurasians, were of a pernicious type and in the category of medical emergencies.

As a special investigation up to March, 1939, extensive use was made of atebryn (mepacrine) to the complete exclusion of quinine. Atebryn by the intramuscular route was the method of choice adopted in all pernicious attacks where vomiting was an invariable complication (0.3 g. intramuscularly at once, and repeated in 6 hours' time); a similar dosage during the following 24 hours, if necessary. Improvement soon occurred, and atebryn 0.1 g. t.i.d. was continued by mouth for a further period of 3 days. In two or three instances a total of 0.9 g. was given in 24 hours without any untoward effect. A very large number of cases were treated. The atebryn was then

supplied gratuitously by Bayer. In the article by Hughes and Bonford no reference is made to the use of mepacrine by the intramuscular route.

The alarming complications as quoted by various authors—vide R. Brierclyffe, "Malaria in Ceylon," *Lancet*, 1935, 2, 1078—were not encountered in any of the nationalities treated.

A clinical report to the Experimental Unit at Elberfeld (Kikuth) on the extensive use of atebirin in malaria has no doubt been destroyed in the ruins of that area.—I am, etc.,

WILLIAM I. GERRARD  
(Formerly of Hong Kong University).  
Kingseat, Aberdeen.

### Shock Therapy

SIR,—I have read with interest Dr. Winnicott's letter attacking electric convulsive therapy on "ethical" grounds. Some of the replies emphasize the danger of further subdividing psychiatry by useless controversies. May I be permitted to add a note on this subject based on impartial observation of various forms of treatment in a large neurological out-patient department?

I have been privileged in the course of my work to meet leading exponents of several schools of psychotherapy, including psycho-analysts trained in Vienna, and to see some of the excellent results they all obtain even under wartime conditions. None of them, so far as I know, holds the view expressed by Dr. Winnicott. So Dr. Winnicott is to be congratulated on expressing himself so candidly and clearly in order that others who think as he does—even if only in some degree—may be encouraged to voice their opinions and so ventilate a natural and widespread feeling of revulsion from electric convulsive therapy. This is specially prevalent among those who know it mainly by name (horrible enough), and have no practical acquaintance with its results. Others have seen it used in the wrong cases, or, again, have heard of histological findings in rabbits subjected to formidable test doses.

Since the advent at the West End Hospital for Nervous Diseases of an out-patient unit for electric convulsive therapy, under the direction of a psychiatrist of considerable experience in treatments of this type, there has emerged in our hospital a new field of success. In my personal experience depressed patients, formerly inaccessible to other forms of treatment, even if suitable for out-patient treatment at all, and not infrequently refusing the only safe recommendation (treatment in a mental hospital), dragged on or curtailed their miserable existence without hope of succour. What use was it to assure them that they would *probably* recover if only they could put up with it a few months longer? 5,000 people in this country commit suicide annually, a perhaps not inconsiderable proportion of these suffering from depressive illnesses. Can it be "unethical" to save a few of these lives?

Of the first 50 cases treated at this hospital, all without complications, 34% returned to normal on an average of four weekly treatments, and a further 36% greatly improved. In every case care was taken not to pursue the treatment if there were not early signs of improvement. It need hardly be emphasized that, as in other branches of medicine, proper selection of the cases combined with care and skill in administration is essential for the best results.—I am, etc.,

A. GREY CLARKE,  
Medical Registrar, West End Hospital for Nervous Diseases.

### Obstetric "Shock"

SIR.—Drs. Mills, Kidd, and Dowsett (Jan. 22, p. 129) are reviving the doubts expressed by the French obstetrician Marc Rivière, who gave the title "Existe-t-il un Choc Obstétrical?" to a paper published in *Rev. franç. Gynéc. Obstét.* in 1924. Having gone over the records of 24,800 births which had taken place at the Vienna University Clinic between 1921 and 1930, I took pains in a monograph on obstetric shock ("Geburtsschock," *Wien. klin. Wschr.*, 1930, 1562) to differentiate between shock-like conditions occurring shortly after delivery and "true obstetric shock." Shock-like conditions after delivery may be due to haemorrhage, embolism, eclamptic toxæmia, and obstetrical manipulations such as version, Credé's expression or manual removal of the placenta, reduction of inversion of the uterus, etc. True obstetric shock was described as a variety of surgical shock occurring from

one to three hours after delivery, and closely resembling secondary or wound shock in its symptoms and signs. It is only diagnosed after careful exclusion of the conditions mentioned, and is probably due to absorption of toxic substances (? histamine) from the placental site, producing changes in the distribution of circulating blood. It occurred once in just over 4,000 deliveries.

Drs. Mills, Kidd, and Dowsett are doubtless right in regarding a great proportion of shock-like conditions occurring after delivery as due to haemorrhage. Apart from these cases, however, every experienced obstetrician occasionally sees patients in whom the shock is quite out of proportion to the (personally observed) amount of blood loss. The fact that these cases of true obstetric shock respond to blood transfusion (or infusion of a 10% glucose solution) does not prove that their condition is caused by blood loss, for surgical shock, of which obstetric shock is but a variety, may occur with a very slight loss of blood and still respond well to blood transfusion.—I am, etc.,

Bedford

NICHOLAS ALDERS.

### Mastoiditis in Infants

SIR.—In answer to Dr. R. Palmerston Rundle's letter (Jan. 15, p. 93) I would suggest that if he were to open the mastoids post mortem of babies under 1 year old who are supposed to have died from gastro-enteritis his opinion that mastoiditis is rare would be reversed. He states he has not seen a case of acute mastoiditis among the children he treats. In my paper I was careful to point out that the physical signs of acute mastoiditis as seen in elder children do not occur. In order to diagnose the condition before death the physical signs enumerated in my paper must be recognized. It is possible that Dr. Rundle has failed to diagnose a condition which nevertheless was present.—I am, etc.,

Birkenhead

P. W. LEATHART.

### Actinomycosis with Lung and Liver Involvement

SIR.—Mr. Hubert Chitty (Jan. 22, p. 115) cites a case of recovery from actinomycosis of the liver, and says that he can find no report of a similar recovery. Personally I had a case which might reasonably be classed as a similar one, although many phases occurred in the history, and it began primarily in the right lung, infecting the liver, and lastly the structures in the right iliac fossa.

The patient was a fruiterer who had his own horse and cart and had to groom the former after delivering his wares. He developed a right basal pneumonia which resolved so slowly and incompletely that he was sent to Manchester Royal Infirmary for x-ray examination. I have no records of the actual findings, but they were to the effect that resolution was incomplete and there was evidence of fibrosis with bronchiectasis. A state of ill-health resulted for months, with partial incapacity and a lot of expectoration, which was not found to be caused by frank tuberculosis.

After some months of poor health the patient developed pain in the right hypochondrium—not severe but continuous, with slight increase of temperature. He was put to bed and expectant treatment resorted to. The pain, which had been high up in the abdomen, settled in the right iliac fossa, and there was marked tenderness over McBurney's point. He was forthwith sent to Manchester Royal Infirmary and operated on after a tentative diagnosis of subacute appendicitis. An abscess was opened, but it was impossible to remove the appendix, and the patient was eventually sent home with a small fistulous opening present.

The discharge dragged on, and eventually another collection of pus developed with brawny swelling above the original incision. He was again sent to hospital and again operated on. The whole of the contents of the caecal area were matted together with brawny, oedematous adhesions. On this occasion, however, the true nature of the complaint was recognized, sulphur-like granules being present in the evacuated pus. Eventually the patient was sent home, and large doses of pot. iod. recommended.

He was subsequently bed-ridden for over a year, numerous sinuses developing in the right groin, and even below Poupart's ligament. The right hip- and knee-joints were partially flexed for about two years in spite of massage and gentle manipulation, but as the numerous cloacæ in the lower abdomen healed and the pus became less in quantity, the patient was able to get about with the aid of a stick, and the flexion gradually improved, until to-day there is little evidence even of a limp, and the aid of a stick is unnecessary.

So far as one can observe the condition is completely cured, and as I saw the man only a few days ago looking the picture of health

there is little doubt that the cure is complete, for it is now at least ten years since the initial onset of symptoms. The original infection was either a primary basal actinomycotic lung infection or else a subdiaphragmatic liver abscess, which in course of time tracked down the right psoas sheath and ended in the caecal area before it burst in the right groin.—I am, etc.,

Stockport.

J. G. BENNETT, M.D.

### Toxic Reactions to Sodium Dehydrocholate

SIR.—Sodium dehydrocholate as a 20% solution for intravenous injection has been extensively used for determination of circulation time. It is perhaps the most popular method of measurement. It is described as one of the standard methods by almost all writers on the subject, and has been sufficiently long in use to be a recommended method in such standard works as Fishberg's *Heart Failure* (1940), Paul White's *Heart Disease* (1937), and Samson Wright's *Applied Physiology* (1940). I have found no reference in these works to toxic reactions, nor was there any mention of it in Martindale's *Extra Pharmacopoeia* (1941). The technique has been used freely in this clinic during the last three or four years as a measure of arm-to-tongue circulation in congestive failure, when it has proved a useful indication of progress under treatment, and also in the diagnosis on supposed communication between the right and left sides of the heart. Recently, however, using the standard preparation supplied by a firm whose standards of purity are very high, reactions have been experienced in three patients, and in one of these subsequent death was probably to be ascribed to the reaction. The symptoms were as follows.

No immediate effect beyond that desired—i.e., experience by the patient of a bitter taste—was produced, and the patient complained of nothing for about an hour. There was then a slight rigor followed by headache, nausea, actual vomiting in one case, and a feeling of severe malaise. No alteration in heart rate or rhythm or fall in blood pressure was observed in the two non-fatal cases; in one of these the reaction was only distinctly unpleasant, in the other slightly alarming. In the third case, however, there appeared to be an immediate "collapse," and the nurse who witnessed it could temporarily not feel the radial pulse. By the time the house-physician made his observations (10 to 20 minutes later) the heart rate and rhythm seemed undisturbed and blood pressure was 150/90, having previously been recorded as 170/110. The patient was still distressed, however, with rather rapid respiration rate, and was spitting up a slightly frothy sputum, but not in any large quantities. The sputum was not blood-tinged. A few crepitations were heard at the bases, but these had been observed the day before when the patient had been admitted. An injection of nikethamide had been given at the onset of these symptoms, and oxygen. The patient was then left by the house-physician with no sense of great anxiety, but one hour later suffered again a sudden circulatory collapse and died in a few minutes. No consent for post-mortem could be obtained.

I am informed by the suppliers that occasional toxic reactions have been reported by other observers, and that some investigation is being made as to the cause, but that such reactions are "infinitely few in comparison with the number of ampoules used for estimation of the circulation time and other purposes." The proportion, however, which the reactions we have experienced here bear to the total number of times we have used sodium dehydrocholate, although small, is certainly not infinitely small. Despite the usefulness of the test, it seems inadvisable to use it so long as the possibility of such serious reactions exists. There are other methods which, although perhaps not quite so satisfactory for bedside use, can nevertheless take its place.—I am, etc.,

Inverness.

D. G. LEYS.

### The Septic Finger

SIR.—If I may be allowed a little of the valuable space in your correspondence column I would like to support Drs. Thomas, Mistlin, and Boroda (Jan. 15, p. 98) in their reply to Dr. Bailey's letter (Dec. 11, p. 764) in which he says that he saw only one "over-ripe" septic finger and no cases of necrosis of a terminal phalanx. He was extraordinarily lucky!

Dr. Romer was not wrong in stating in his letter (Oct. 30, p. 556) in reply to Dr. Atkinson's (Oct. 2, p. 432) that "the worst mistakes are not made by 'the most junior house-surgeons,'" as the latter seems to believe. True, as he (Dr. Atkinson) says, "there is much unskilful and even negligent treatment of septic fingers," but as to who is responsible for this I am in 100% agreement with all that Dr. Romer says in his excellent letter.

But since none of these writers has produced any actual figures, I have tabulated the more relevant facts from the first 70 consecutive record cards of the first 70 patients with infections of the hand that I saw and treated myself.

Type of Infection	Number and Percentage	Days Lost by All	Number "Over-ripe"	Average No. of Days for "Over-ripe"	Average No. of Days for Others	Average Difference
Superficial abscess	19 (27.14)	196	6	13.8	6.3	4.3
Paronychia	16 (22.85)	187	3	24.66	7.5	17.16
Pulp	14 (20)	154	2	26.0	8.5	17.5
Tendon sheath	7 (10)	164	2	45.0	14.8	30.2
Lumbrical canal	3 (4.28)	74	2	43.0	15.5	27.5
Septic arthritis	1 (1.42)	48	1	48.0	—	—
Miscellaneous	10 (14.28)	184	3	28.6	14.0	14.6

This table shows that in 70 infections of the hand 1,007 man-days' work were lost, in my opinion at least, 326 (approximately) being avoidable if the patients had been treated earlier with adequate drainage. Not only was there this loss of labour for war production, but in three of the cases which were "over-ripe" (19 in all—i.e., 27%) there was necrosis in a terminal phalanx, as shown by x-ray examination, while most of the remaining 16 have some permanent stiffness and loss of function. Eight of these unfortunate ones had had their fingers "lanced" by their doctors from 2 to 5 days before being sent up to hospital. Each had had a "freezing spray." Surely the ethyl chloride spray can have no place in the treatment of these infections, since they are either (1) so superficial that the dead skin can be snipped off quite painlessly without any anaesthetic, or (2) so deeply seated that this method of anaesthesia cannot enable adequate incisions to be made.

Finally, I would like to reiterate Dr. Romer's observation that "no doctor should go into general practice without having done a casualty job." Being only four weeks away from the end of my appointment as a casualty officer, I am quite convinced that for good all-round experience it is the best possible way of spending the six months before joining one of the Services.—I am, etc.,

London, N.15.

PHILIP HOPKINS.

### Psychiatry at the Cross-roads

SIR.—In view of the growing importance of psychiatry in all branches of medicine the profession should be grateful to Drs. Sargent and Horsley for drawing attention to some of the more unsatisfactory features of mental hospital administration. They mention particularly one question—namely, the inferior status of the "assistant medical officer." The name sums up the position. No official recognition is accorded him of his specialist qualifications. He is an A.M.O., not a psychiatrist. All progressive members of the profession now advocate that in all hospitals, including mental hospitals, the clinical worker should have a status at least equal to the administrator's (both doctors and nurses), and that the clinical affairs of the hospital should be run by a clinical committee.

Time was when in his custodial role the medical superintendent could effectively carry out the duties implied in both parts of his title. There is still a legal fiction that this is so even now. Such is clearly far from being the case, and it is absurd to suggest that any one man can in fact be fully *au fait* with all that is happening in a community which, including patients and staff, may total nearly 4,000 persons in some modern mental hospitals.

We must never lose sight of the old truism that as doctors our first duty is to our patients. Unfortunately it is very easy to do so, as a remark in Dr. Cuthbert's letter illustrates. As a solution of the present difficulties he suggests that the A.M.O. should resign or seek appointment elsewhere in a more progressive district if he meets with opposition. But what of the

unfortunate patient who is not at liberty to resign or seek appointment elsewhere?

The second main factor in the production of those undesirable internal stresses among the medical staffs of mental hospitals to which your correspondents refer is the isolation of these hospitals. The mental hospital is a self-contained world effectively insulated against the real world outside. This barrier must be broken down if psychiatry is to play its proper part in general medicine, education, and industry. All local mental services must be integrated into a national scheme with interchangeability of staffs. The mental service must function as a unit of a general health service on a national scale. Psychiatrists should work in health centres; general hospitals, schools, and factories, as well as in the mental hospital. The mental deficiency and general psychiatry personnel should no longer be rigidly separated, and the prison service should be linked up with the general scheme. Above all, in research, greater efforts must be made to enlist the general research worker with all his technical facilities in the attack on the host of formidable problems with which psychiatry bristles.

The difficulties of Drs. Sargent and Horsley will be solved when, by the breaking down of these barriers, we are enabled to take psychiatry to the patient instead of taking the incurable psychotic to the "A.M.O."—I am, etc.,

St. Mary Cray,

BRIAN H. KIRMAN.

### Intravenous Anaesthesia

SIR,—I have read with interest the article by Drs. F. W. Roberts and B. A. Sellick describing a simple method of intravenous anaesthesia (Dec. 25, p. 813). My interest in anaesthetics is purely from the surgeon's view-point. As the anaesthetics in this hospital are given by house-surgeons, many of whom have no previous experience, it is a matter of necessity for me to interest myself in this branch of medicine and to try to teach it as well as to perform operations (a task I do not approve of). I have been using intravenous anaesthesia since 1936, and I have now given, or rather have been responsible for having given, about 3,000 intravenous anaesthetics without any mortality or even any serious worry about any case.

I do not agree that the apparatus described by your correspondents is so very simple. In the first place it requires the use of a table, which if large probably comes in the way of the surgeon or his assistants, and if small must be of a very sturdy pattern to ensure that it is not knocked over accidentally. The provision of a hand bulb requires fairly frequent attention if one is to ensure that blood does not leak back from the vein and block the needle during the intervals between injection of the anaesthetic solution. I do not see anything cumbersome in a simple metal stand which provides a continuous gravity drip with such an apparatus as a colossal saline bottle with the usual attachment for intravenous drip. With this apparatus the anaesthetist can devote more of his attention to the patient, and the continuous drip eliminates all possibility of blood blocking the intravenous needle. Another point I would like to stress is the necessity for putting three strips of adhesive plaster on the patient's forearm: one across the tube immediately behind the adapter, a second about 3 in. further back, and a third about 1 or 2 in. further on. A thin pad of ribbon gauze under the outer end of the needle and the adapter will be useful in most patients, especially thinner subjects. I do not use pressure tubing as described by your correspondents in para. 6: about 4 in. of ordinary good tubing is quite good enough, and has the advantage that it permits the easy insertion of the needle, injecting the anaesthetic agent. It is also easy for the anaesthetist to compress this tubing on the distal side while injections are being given. For operations in the upper part of the body the vertical stand has the further advantage that it can be moved rapidly out of the way. I have never seen a needle slip out of the vein after the adhesive strips are applied properly to the tube and the patient's arm, and the colossal drip-saline apparatus is the essence of simplicity.

Intravenous anaesthesia does not appear to be very popular in this country, judging from the number of house-surgeons who come here and who have never seen it given. So far

as I can estimate this is due to failure to apply a proper technique, and especially pre-operative medication. For short operations of ten to twenty minutes' duration I do not think it has an equal. It has the great advantage of putting the patient asleep in one minute without any unpleasant feeling whatever on his or her part, and it provides muscular relaxation not usually possible with gas.

The highest dosage I have used has been 34 c.cm. of 5% pentothal. All patients receive a preliminary dose of morphine varying from 1/6 to 1/2 gr., with atropine, according to the stature of the patient. Patients who do not appear to be recovering fairly quickly receive a dose of intravenous coramine, which has proved a rapid restorative. The only unpleasant sequel is vomiting, which occurs in about one-fifth of the patients. The vomiting is not of a very serious character and in my opinion is very frequently due to morphine, as about 10% of all patients have a tendency to vomit before they receive any pentothal.

Finally, I am sure (as this important subject has been very seldom dealt with in the *Journal*) many of us would be glad to have some further information from expert anaesthetists such as Drs. Roberts and Sellick on the maximum dosage they employ in the administration of intravenous anaesthesia.—I am, etc.,

J. F. O'CONNOR,

Surgeon, Limerick County Hospital.

### Population Problems of India

SIR.—Prof. Blacklock has raised a very important topic in his article in arguing it will be necessary to give attention to the population problems of India. However, his essay is based on an uncompromising acceptance of the validity of the Malthusian doctrine, backed only by the rather hypothetical support of Henry George. But neither of these is to-day usually regarded as the greatest of economists or even of experts on population problems. On the contrary, Malthus, whom facts have nowhere proved correct, is regarded as a subject of purely historical interest.

As regards Western Europe there is no doubt of the falsity of his theories. In India, too, he has been disproved: Prof. Blacklock quotes the increase of the population 1931-41 as being 15%. Prof. R. R. Kuczynski, "the most distinguished living authority on problems of population," has thrown considerable doubt on the accuracy of the Indian census figures in the *Statist.*, Dec., 1937; but even if the figures are accepted, while India's population 1921-31 increased by 10.6% the U.S.A. increased by 14.2%. From 1880 to 1930 India's numbers rose by 31.7%, while England and Wales bore 53.8% more. Moreover, Indian food production increased by more than the population (R. Mukerjee, *Food Planning for Four Hundred Millions*, 1938, pp. 17 and 27). Prof. P. J. Thomas in the *Times* of Oct. 24, 1935, summed it up: "Population has not outstripped production. . . . Those who are alarmed about 'the devastating torrent of babies' in India will do well to direct their attention to improvements in the distribution of the national income, in the quality of consumption, and in the geographical distribution of population, and to other allied matters."

I would submit that there are many points of the greatest significance which are overlooked in Prof. Blacklock's thesis, and I beg to draw attention to some of them.

1. He omits all consideration of the possible effects of industrialization in India. While it might be correct in global estimations to concentrate all attention on agricultural products as the basis of human life, it is certainly wrong to do so in considering one country, even though it be as vast as India. Particularly is this a potentially great source of error in India, since she is richly endowed with many of the raw materials of industry, the development of which cannot be long delayed. Furthermore, as the Hot Springs Conference Report, Section II, states, "The real clue to the solution of the problems of agricultural over-population lies in industrialization. . . . [it] is also necessary if we are to raise the general standard of living."

2. New scientific agricultural techniques have demonstrated the enormous potentialities of increased production—the verbalization of grains enabling otherwise climatically unsuitable areas to produce food grains, artificial insemination with its

prospects of improved stock breeding, heating of soils by electric wiring—all these are the very first-fruits of the application of science to agriculture, and give promise of new and limitless production possibilities.

3. There is an observed tendency for urban populations to be less fertile than rural populations, so that as the industrialization which it is suggested in 1 may take place, it might be accompanied by a reduction in the birth rate.

4. Man is both consumer and producer. To-day in India 50% of all deaths are of children under 10. From another standpoint this means that a great proportion of the population never functions as fully efficient producers. Every lengthening of the span of life, if it is coupled with adequate nutritional intake, increases the producer period of a man's life.

5. As emphasized at the Hot Springs Conference, only a satisfactory diet will enable a man to function as an efficient producer, and, to quote once more from the admirable section reports of that conference: "Given the will, we have the power to build in every nation a people more fit, more vigorous, more competent; a people with longer, more productive lives, and with more physical and mental stamina than the world has ever known." It is on this goal of expansion, rather than on any restriction, whether of production or of population, that I suggest we should fix our gaze.—I am, etc.,

R. G. FORRESTER,

Chairman, Research Committee, Association of Scientific Workers.

### Allowances for Tuberculous Persons

SIR,—There has been some criticism of the scheme for tuberculosis allowances, the guiding principles of which were adumbrated in Ministry of Health Memorandum 266 T, a document that may yet prove to be the foundation of a "charter" for the tuberculous. Everywhere—from the House of Commons to the dispensary waiting-room—one learns of the shortcomings of a scheme which the Government is among the first to own is not comprehensive. Two main barrages of criticism have been laid down: (1) that the scheme excludes the "chronic" case; (2) that non-pulmonary cases are ignored.

Adult pulmonary tuberculosis is, in the main, a chronic, fluctuating disease. The most acute types may be fatal within weeks or months. Is it not therefore wrong, for the purposes of the treatment allowance, to make a distinction between "chronic" and "acute"? In the most severe types (than which no type is less "chronic") no tuberculosis officer would recommend payment of allowances. The criterion for participation is surely whether an individual, by undertaking treatment, has a reasonable prospect of being restored to working capacity within 1 to 2 years. Where the prognosis is less favourable many think that such patients should also receive benefit. This raises the larger issue of whether our chronic sick population in the future should be entitled to pensions from the State. It would be untimely and inequitable to grant pensions to our chronic phthisical population while leaving out our chronic neuritis, cardiacs, arthritics, etc. It cannot be said that mere provision of allowances to those suffering from chronic phthisis would alter by one jot their potential infectivity or others.

Non-pulmonary cases are generally not a danger to public health, and hence joint tuberculosis requires prolonged institutional treatment. For these and other reasons I do not think that they should be included in the present scheme. If they were, such diverse conditions as Pott's disease, renal and abdominal tuberculosis, lupus, iridocyclitis, would all carry some entitlement to benefit. Has the tuberculous synovium to be favoured while the "rheumatoid" one is not? Should we aid our *tubercle bacillus* and not our abdominal Hodgkin? There is no halo round the tubercle bacillus that it should be expected to receive such priority.

Mem. 266 T, essentially a wartime measure, is a beginning that is welcomed by all tuberculosis workers. Few are they who, if given a free hand, could not improve the scheme. No Government in the future can turn back on a road already travelled upon up to (and beyond) the first milestone. We can therefore expect with confidence that Mem. 266 T is the first instalment of a programme in which it will be recognized that our "chronic sick" population, including the chronic tuberculous, is the responsibility of the community.—I am, etc.,

HE

R. HARDY.

### 58 Stones in the Urinary Bladder

SIR,—In December last there was admitted to the Waveney Hospital, Ballymena, a man aged 67 who complained of pain and frequency of micturition with the frequent passing of what he called small flints. Of these he stated he had passed three on the day before admission. His trouble dated back for almost twenty years. On abdominal palpation a hard tumour the size of a foetal head could be felt rising out of his pelvis. X-ray examination showed an opaque mass of that size apparently faintly divided into separate masses about the size of bantams' eggs. On Dec. 29 I removed from his bladder, through a suprapubic approach, 58 stones weighing altogether

20½ oz. The largest was well over 1½ oz. in weight and there were 11 which weighed over 1 oz. each. I enclose a photograph of the stones, which shows their shape and size when compared with an inch tape measure included in the photograph.

This is a record number of bladder stones so far as I am concerned, and I have been wondering if it approaches a real record. The patient is doing well, and when after seeing the stones he had expressed his astonishment at their number he made one request. He stated that his family had thought that he had been exaggerating his sufferings before he was sent into hospital, so he specially asked that the stones should be shown to his wife, stating that surely after seeing them she would show a little more "generosity" towards him. I presented him with a copy of the photograph, which he shows to people presumably to stimulate their "generosity".—I am, etc.,

Ballymena, Co. Antrim.

J. ARMSTRONG.

### Artificial Vagina

SIR,—I have read the article by Mr. Thomas O'Neill on congenital absence of the vagina treated successfully by the Baldwin technique (Dec. 11, p. 746) with great interest. However, I have missed one publication among the references. It concerns an operation for atresia vaginae performed, and published in the *Arch. Gynäk.* in 1923, by G. A. Wagner, working in Prague at that time.

The case concerned a woman of 27 with atresia vaginae operated on at the age of 19 for haematocolpos and haematometra. On examination there was found a vagina which was divided into two parts by a transverse scar. The lower part was about ¾ in. long admitting the tip of the finger, the upper part was about 2 in. long and connected with the lower part by an opening just admitting a probe. The uterus was of normal size. After excision of the scar a piece of rectum was used to form an artificial vagina following Schubert's technique.

After the operation the patient menstruated regularly until the spring of 1922, when she became pregnant. Arrangements were made to perform a Caesarean section at term in order that the artificial vagina should not be damaged. As the patient lived in the country and the labour pain started a short time before the estimated date she was unable to get to hospital for the operation. However, a living child of 6 lb. was born with the aid of forceps and episiotomy. Apart from this episiotomy the artificial vagina was undamaged. The woman delivered another living child by natural means, but unfortunately I could not find the references for the second pregnancy.—I am, etc.,

London, N.W.1.

V. GOLD, M.D. Prague.

# Babies in Hospital

SIR.—I am in entire agreement with Dr. Margaret Dunstan in her opinion that "hospital wards can be very dangerous places in which to treat infants" (Jan. 22, p. 131). Out of a series of 190 cases of infantile diarrhoea treated at the West Middlesex Hospital between April, 1942, and April, 1943, 84 were transferred direct or recently discharged from institutions—maternity wards, children's wards, and wartime day nurseries. The total mortality was over 50%.—I am, etc.,

PATRIA GARDNER, M.D., M.R.C.P.  
Asst. M.O., Oxfordshire County Council

## Obituary

W. W. C. TOPLEY, M.D., F.R.C.P., F.R.S.

We much regret to record the sudden death on Jan. 21, at the age of 57, of Dr. W. W. C. Topley, a brilliant bacteriologist, a great administrator, and for more than twenty years an outstanding figure in English medicine. His career as a student was marked by conspicuous success. At Cambridge he was a scholar of St. John's College and was placed in the first class of the Natural Sciences Tripos. He qualified in 1909. While at St. Thomas's Hospital he won the Murchison Scholarship of the Royal College of Physicians, and, influenced perhaps by the vigorous personality of L. S. Dudgeon, as were others of his generation, he began his life's work as assistant director of the hospital laboratories. A year later

he became director of the department of clinical pathology and lecturer on bacteriology at Charing Cross Hospital, and from that time onwards became more and more engrossed in bacteriology. As a captain in the R.A.M.C. he was appointed bacteriologist to the British Sanitary Commission in Serbia, and in 1919, on his election to the Fellowship of the Royal College of Physicians, was invited to deliver the Goulstonian lecture, an unusual honour for a laboratory worker.

In 1922 Topley's reputation as a bacteriologist and as a teacher was recognized by his election at an early age to the

chair of bacteriology in the University of Manchester, where during the following five years his vigorous capacity for constructive administration found congenial and profitable opportunity. He planned and brought into existence an admirable course designed to give young graduates a sound training in the principles and practice of bacteriology, and it provided the model for the courses for the academic diploma in bacteriology of the University of London. In 1926 he delivered the Milroy lecture, and his election in 1927 to a professorship in the University of London and the directorship of the Division of Bacteriology and Immunology in the newly established London School of Hygiene and Tropical Medicine came as a fitting and very popular recognition of the position which he had made for himself among English-speaking bacteriologists. The appointment at the School of Hygiene provided Topley with a larger field for his gifts as a teacher and as an administrator, and enlarged opportunities for collaboration in research with his colleagues and pupils as well as with friends in other London laboratories.

In his original work he devoted himself to the investigation of the factors which influence the spread of bacterial infection, and he invented and used entirely new methods for the study of epidemics in a population of laboratory mice. He was one of the first to use experimental methods in the study of epidemics, and he became the authority on the subject. During

the twenty years 1919-39 Topley in association with colleagues and pupils carried out a number of ingeniously planned experiments which required skill and patience in their performance, and judgment in their interpretation. He made new observations and was able by the use of controlled experimental material to amplify and check conclusions derived from the observation of naturally occurring epidemics in man. His contributions to bacteriology derived their inspiration from the study of the problems which presented themselves to him in the course of his epidemiological inquiries. In 1921 he described an ingenious method of obtaining cultures from single bacterial cells, and in the same year published a paper on the interrelationship of members of the Salmonella group of bacteria. He contributed several papers on the complex problems arising from the antigenic analysis of the types responsible for enteric infections, and on the susceptibility of these micro-organisms to bacteriophage. The studies of experimental epidemics provided an opportunity for the investigation of the influence of prophylactic inoculation under controlled conditions, and of the effect of change of diet on a population of mice exposed to infective disease. Of particular interest is his more recent work undertaken in association with H. Raistrick and M. E. Delafield on the immunizing potency of antigenic components isolated in a state of relative chemical purity from *B. typhi murium* and from *B. typhosum*. In a short paper published with J. Wilson and J. T. Duncan it was shown that, in a mixture containing two distinct types of bacteria and their two homologous antisera, the resulting aggregates were of two distinct types, each containing individuals of one or the other species. Mixed aggregates did not occur.

Topley wrote well, and *An Outline of Immunity*, published in 1933, contained within 400 pages an informative review of the then state of knowledge in this subject. To-day it is still good reading. *The Principles of Bacteriology and Immunity*, which he wrote with G. S. Wilson, became on the day of its publication the standard work of reference in the English language, an indispensable source of accurate and up-to-date information. Topley's communications to the Pathological Society will be remembered by its members as examples of exposition, short and to the point, and often flavoured with a restrained and half-concealed humour.

Early in 1939, at the request of the Medical Research Council, Topley undertook the preparation of plans for the mobilization of bacteriological experience to meet the probable needs of impending war. He had a gift for making plans, and the rarer gift of making plans which worked and of choosing the right men to carry them out. The Emergency Health Laboratory Service, a fitting memorial to his bold but always constructive planning, should survive the period of the war to the great advantage of the medical services of the country. His election to be Secretary of the Agricultural Research Council—a remarkable tribute to his administrative genius—came as a shock to his medical colleagues, to whom his help and co-operation, always freely given, had come to mean so much. In 1942 he was awarded a Royal Medal of the Royal Society for his outstanding work on experimental epidemiology and immunology.

Staunch and loyal to his friends, in whose problems and difficulties he took an interest which was sometimes critical but always helpful, he disliked humbug, especially in high places, and was always ready to give encouragement and help to younger men who came to him for advice. We who have known him and enjoyed his companionship must mourn a much-loved friend, and medical science can ill afford his loss.

We are indebted to Prof. MAJOR GREENWOOD for the following appreciation: A friendship of more than twenty years and close scientific collaboration down to the outbreak of war united me to Topley. Of the merits of our work on experimental epidemiology it is not for me to speak, but a few words on the nature of the collaboration may be said. The whole credit of initiation belongs to Topley and all the improvements of experimental technique were his. The part of the statistical collaborators was mainly critical and technical; when, as sometimes happened, one of us suggested a new experiment, it was Topley who converted a project into a real experiment. His skill in devising a set-up was great; but others can speak of his scientific genius with more knowledge than I; it is of him as a human personality that I wish to say something. Bagehot said of Macaulay that he never changed, that what he was at 30 he still was at 50. Bagehot intended this to be disparaging—he spoke of Macaulay's inexperienced nature; the sense in which I apply it to Topley is not disparaging but, I think, the key to his success. He never lost the eagerness which he showed as a young man.

When Topley began his work on experimental epidemiology in 1919 he was under 35; his wartime experience of a great epidemic and the vagueness of "classical" epidemiology—a mixture of

(Elliott and Fry)

archaeology and folk-lore he once called it—stimulated him to try experimentation. Perhaps he may have expected quicker results from experiment combined with the new biostatistical technique of Pearson and his pupils than an older man would have done. If so, he quickly readjusted himself, and realized that the research would be long and could not be spectacular; that at first one could only verify natural experience; then, as the technique became more precise, make small additions to knowledge; never, within the span of a lifetime, solve completely the great problems. But his enthusiasm never flagged. He could bear cruel disappointments—the ruin of a long experiment by an accidentally introduced infection, or, still more exasperating, the demolition of an apparently established hypothesis by a “natural” variation—with perfect good humour. That is why he has left a technique which others whom the gods do not love can use. The hardest part of the research is over; now duller people can raise the flower for they have got the seed.

It may be said that Topley's enthusiasm was confined to a relatively narrow range of subjects, that his scientific philosophy was Victorian. Perhaps that is true; he read widely, but never, I think, had much emotional sympathy with methods of seeking truth which did not depend on controlled laboratory or field experiments. However, in these days of slovenly omniscience one may well respect a man who resolutely ignores what does not interest him, who never pretends to know what he does not know. We have lost a man whose intellectual honesty was unshakable, who always expressed his opinions clearly.

“... Let me not live  
Atter my flame lacks oil, to be the snuff  
Of younger spirits,”

is a prayer Topley would have put up; he has gone before the meanest spirit could hint at a lack of oil, and science will be the poorer. His friends will cherish more personal memories—his keen enjoyment of the sea and the open country; the solemnity with which he denounced idols of the market place; the twinkle in his eye when one asked: “A bad man, Bill?”; and he would reply: “A very bad man.” It was quite possible to disagree with Topley, very difficult not to love him.

H. M. CLARKE, M.B., B.Ch.

We regret to announce the death on Jan. 11 in a nursing home at Reading of Mr. H. M. Clarke. Born in 1878, Henry Milford Clarke received his early education at Wakefield Grammar School, from which he entered Clare College, Cambridge, with a classical scholarship in 1897. He graduated B.A. in the Natural Sciences Tripos in 1900, B.Ch. in 1905, and M.B. in 1906. From Cambridge he went to Guy's Hospital, where he was house-surgeon to Sir William Arbuthnot Lane and to Mr. Frank Stewart and was out-patient officer. In 1907 he went to Reading, where he soon entered upon his long association with the Royal Berkshire Hospital, which continued until ill-health compelled him to retire from practice a few years ago. He held the posts of surgical registrar, surgeon to out-patients, and finally surgeon. Clarke was incapacitated by illness some little time before the age (60) for retiring from the honorary surgical staff; when he reached that age he was elected an honorary consulting surgeon to the hospital. He was an active member of the Reading Zoological Society, which he joined in 1908 and of which he was president in 1933-4. During the last war he held several surgical appointments in succession, serving from October, 1914, to May, 1919. He was seconded to the French Army base hospital at Rennes; surgeon to the *Aquitania* until the evacuation of the Dardanelles; surgeon at a casualty clearing station in France, where he was severely wounded in 1917; and surgeon specialist in Malta.

In his younger days Clarke was keenly interested in rugby football and rowing. He rowed in his college boat in the May races, the crew achieving the coveted four “bumps,” and for the Reading Rowing Club. He also played for the Berkshire Wanderers (Rugby) Football Club. Clarke was a very modest man, and only those intimately associated with him in surgical practice could realize fully his surgical skill and his devotion to surgery. His long service to the Royal Berkshire Hospital was rendered in the quiet, unobtrusive manner characteristic of him. In sport he played with the true team spirit, shunning all personal notoriety. He was a deservedly popular man, and his passing is mourned by a wide circle of friends and patients. He leaves a widow, to whom deep sympathy is extended by all who knew them and enjoyed their friendship.

Mr. W. BERNARD SECRETAN, consulting surgeon to the Royal Berkshire Hospital, writes:

Clarke was a man of extremely modest character, good-natured to a degree and with a charming manner. I should think he never had a quarrel. He was a man of parts, but owing to his unassuming character this was not sufficiently appreciated. He had an excellent knowledge of several languages and was accustomed in his vacations to visit Continental clinics to improve his medical outlook. He was a Fellow of the Zoological Society and was intensely interested in all animal life, and particularly in bird life; he had a very fine collection of shells, on which he was quite an authority. He was an extremely good surgeon, both as diagnostician and operator; he would, I think, have become even better known in this direction had he been less inclined to self-depreciation. He was unfortunately cut down in his prime by an illness which left him incapable of work for a good many years before his death. Everyone at the Royal Berkshire Hospital will remember him with affection.

We regret to announce the death of Dr. JEAN MARR on Jan. 2. Jamesina Jane Marr was born in Banffshire, Scotland, on Jan. 19, 1875, and qualified M.B., Ch.B. at Edinburgh in 1907 and took the D.P.H. at the same medical school in 1909. She held resident posts at the Edinburgh Hospital for Women and Children and the Aberdeen Sick Children's Hospital and was for a time assistant school medical officer at Aberdeen. For over 30 years Dr. Marr was in practice in Glossop Road, Sheffield, until compelled by failing health to give it up in 1937. She was a member of the B.M.A. until her retirement as well as of the Medical Women's Federation and the North of England Obstetrical Society. Her practice was largely devoted to the treatment of women and children, and she became locally well known as an obstetrician. She was a deeply loved practitioner who, it can be said, devoted her life to her profession. She was, in short, the real family doctor whose advice was sought on many problems not necessarily medical. She was extremely generous to the less-well-off, and she will be affectionately remembered by a large number of women who received treatment from her but never an account.

## Medico-Legal

### WHAT IS A SHOP?

A salesman came twice a week to the same pitch in the uncovered part of the Leeds City Market and set up a stall, consisting simply of a board supported by two trestles. One day he sold to an inspector of the Pharmaceutical Society some medicine of a kind which under the Pharmacy and Medicines Act, 1941, s. 12 (2), may not be sold by retail, except at a shop. Prosecuted before the stipendiary, he argued in his defence that his stall was a shop. The magistrate held that he was wrong and convicted him, but agreed to state a case for the Divisional Court. The Act refers for the definition of a shop to the Shops Act, 1912, which says that a shop includes any premises where any retail trade or business is carried on. The salesman seemed therefore to have a fairly strong case. The Lord Chief Justice, however, insisted on considering the definition in relation to the objects of the Pharmacy and Medicines Act and its other provisions. The Act seemed to him clearly to provide machinery by which the status of the profession or trade would be raised or maintained. In many passages Parliament seemed to have contemplated that the “shop” dealt with in the Act should be a place defined by precise limits upon which or upon part of which there was some sort of a structure. He thought it necessary to consider, not only whether a retail trade was carried on, but whether there were any “premises” where it was carried on. He did not find any particular help in the authorities. He agreed with an earlier dictum that the Legislature meant to give (in the Shops Act) an extended and unnatural meaning to the word “shop,” a meaning that went far beyond the popular and recognized meaning. Nevertheless, he did not find that the words “premises where a retail trade is carried on” were so wide as to mean that a place unbounded by any ascertainable marks or fences, with no structure except two trestles and a board, with no continuity or regularity except business twice a week, was a shop. The court therefore held that the salesman had been rightly convicted of infringing the Pharmacy Act. The decision will probably put a stop to a good deal of informal trading in medicines which the Act was designed to check, but it suggests the interesting question: If a pharmacist's shop is destroyed by a bomb, is it unlawful for him to carry on his business on the cleared site, or in front of it, on an improvised counter? If it is, he is at a disadvantage from which other retailers do not suffer.

## Medical Notes in Parliament

### Employment of Disabled Persons

The House of Commons, in Committee on Jan. 18, began consideration of the Disabled Persons (Employment) Bill. Mr. RHYNS DAVIES moved an amendment to include in the definition of disabled persons those suffering from neurosis. He said that cases of neurosis were among the most difficult to deal with in rehabilitation, and he was not sure that, as the Bill stood, the Ministry of Labour could deal with them. The last report of the Ministry of Pensions showed that the largest single group of disabled persons still remaining on their books was that of sufferers from neurosis. Mr. TOMLINSON said there was no doubt that the definition in the Bill covered both physical and mental disease, and Mr. Davies was wrong in saying that mental deficiency would not come under the Bill. Several members having supported the amendment, the ATTORNEY-GENERAL said it was the intention to include people whose mental infirmity arose from mental disease, as well as those whose mental infirmity arose not from disease but from a congenital condition. The amendment was withdrawn. Mr. TOMLINSON then moved a Government amendment, defining "disease" as including a physical or mental condition arising from imperfect development of any organ. The purpose of the amendment was to prevent anybody being excluded. For instance, the imperfect development of the optic nerve might cause blindness, and where the disability was congenital it would be included under his amendment. It was intended to embrace every reasonable case. The amendment was agreed to.

A long discussion took place on an amendment moved by Major MANNINGHAM-BULLER, which, he said, would ensure that if there was to be a "queue" for admission to the training courses the war-disabled should be at the right end of it. The number of persons who would require training must be uncertain, and he did not want to see the war-disabled kept waiting. Sir IAN FRASER said that one of the factors which had caused an almost unanimous second reading of the Bill was the assurance by the Ministry of Labour that if it proved to be necessary they would, by administrative action, see that ex-Service and war-disabled persons would be first considered. Mr. BEVIN said he made that statement with a view to binding his Department not only during his term of office but in the administration of the Bill permanently. He could carry out the principle better administratively if no limitations were put on him. If members would agree with him that this was an industrial and not a pensions matter, he would agree between now and the report stage to find words to meet their desire and to give effect to the intention and pledge of the Government. If they would agree to the use of words such as "preference for persons who have served" instead of merely "war-disabled," he would be happy to meet them. The amendment was negatived.

Sir IAN FRASER moved an amendment to provide that war-disabled persons should be separately recorded in the register, so that ex-Service men and others to whom it was proposed to give a prior place should be clearly recognized. Mr. TOMLINSON said the Department already had this power, and Mr. Bevin undertook that the war-disabled should be put into proper categories so that they might be recognizable. The amendment was negatived, and the consideration of the Bill was adjourned.

### Education Bill

Mr. R. A. BUTLER on Jan. 19 moved the second reading of the Education Bill. He said this Bill completely recast the law as it affected education. The Acts of 1899 and 1921 were repealed. The Bill offered an opportunity to every child to pass through the primary and secondary stages of education, and would give all children over 11 opportunities for making the most of their natural aptitudes. He hoped that from the Bill would arise a healthy development of nursery schools or classes. A complete revision was proposed in the law for dealing with the handicapped child. A duty was to be laid on local education authorities to ascertain all children who, because of disability of mind or body, needed special attention. Mr. Butler proposed to abolish, for educational purposes, certification under the Mental Deficiency Acts. No child who could be dealt with within the education system should in future be described or treated as mentally defective. Only those who could not be educated and those likely to need supervision after leaving school would be appointed to the mental deficiency authorities. Categories of handicapped and backward children, for whom special provisions should be made,

would be defined in regulations and not in the Act to enable advantage to be taken of new developments in medical knowledge or in psychological diagnosis and practice. Children with slight disabilities might be taught by special methods adapted to their needs in ordinary primary and secondary schools. For the more seriously disabled he looked for an extended provision of special schools through local authorities and voluntary endeavour. He was taking power to give additional financial help to the latter. One clause of the Bill gave parents the right to ask for medical examination of any child over the age of 2 with the object of securing special educational treatment.

### Clause 46

The Bill imposed a duty on authorities to provide meals and milk. The proposal was drawn on broad lines so that it could be adjusted to the Government's future decision on family allowances. Clause 46 proposed that local education authorities should be under an obligation to see that all children attending school or a young people's college maintained by such an authority should be able to obtain free medical attention other than domiciliary treatment. Parents would be under an obligation to submit their children to medical attention. Every effort would be made to enable children to take advantage of modern medical and dental treatment. There was no foundation for the fear that the Bill would deprive local authorities of responsibility for medical treatment and confine the work of the school medical officers to medical inspection. Clause 46 was likely to give school medical officers and staff a greater responsibility for the treatment of children. The Government trusted that with the development of the new national health service the duties of school medical officers would be widened and that the school medical service would become part of the general health services of the nation.

The biggest change would be a regular and careful inspection of boys and girls who had left school and entered employment. At present there was no continuation of the medical service to look after them. Co-operation between the school medical staff and the agencies advising young people on choice of employment and physical welfare in industry was to be centred in the young people's colleges. The Government was keen to re-enact, with modifications, Mr. Fisher's proposals for continuing education. The age range in the young people's colleges would be up to 18 for a school-leaving age which at first was to be 15 and later on 16.

Debate continued on Jan. 20, and the Bill was read a second time.

### Regulation 33B

Dr. SUMMERSKILL on Jan. 20 drew attention to the increased incidence of venereal disease in the United Kingdom. She said that Mr. Ernest Brown had refused to take more effective action to reduce this incidence. After six months in which Regulation 33B had been in operation two men had been informed against and 64 women. In addition, 1,780 people had been reported, but by only one person in each case, which meant that 33B did not apply. She was told that the number of new cases in 1942 was 120,000. Any other disease which was a menace to the community was notifiable. Why not this? In Scotland the County Council of Lanarkshire and the burghs in that county had agreed to support a scheme of compulsory notification and treatment. The city of Glasgow was moving in the same direction.

Dr. HADEN GUEST was forced to conclude that the Ministry had not sufficiently stimulated the activities of medical officers of health and other health authorities in this matter. Such officers and authorities were often not particularly interested in prevention of venereal disease. There had been complaints in Allied circles about the numbers of their troops who had been affected in this country, particularly in London. Dr. MORGAN said that in Chicago, when there was compulsory notification and treatment, the figures of the disease went up higher. This had been the case all over America where these measures were tried.

Miss HORSBROUGH, replying to the debate, referred to the Edinburgh Bill, introduced into the House of Commons some years ago, on this subject. What was the best method of getting those affected to go for treatment at the earliest moment? The Ministry had tried to ensure that if people were infected they knew something about the disease and the urgent necessity for treatment at once. If people knew they would have to go to the doctor under a compulsory scheme they would decide to wait because they would not want to be caught up in a compulsory scheme. The Ministry had to let knowledge grow. Without that it would not succeed, whether the country had compulsory notification or not. The figures quoted by Dr. Summerskill were of those who had refused treatment and on whom a notice had then been served. In about half the cases where there had been two notifications the individuals

came forward voluntarily when persuaded. Two names of contacts were required if action was taken compulsorily under 13B, but not otherwise. Difficulty had been experienced by medical officers who were uncertain about the legal aspect. There was an idea that if they interviewed people and asked them whether they were aware they had this disease, there might be subsequent actions for slander or defamation of character. Local authorities had been told that if they instructed the medical officer of health to take such action he was protected.

#### Advisory Committee on Domestic Labour

Mrs. CAZALET KEIR on Jan. 20 asked the Minister of Labour about the progress of his plans for supplying domestic labour to hospitals and other similar services. Mr. ERNEST BEVIN said he found it necessary to give first priority to domestic work in connexion with the care of the sick and wounded, the old and infirm, and young children. He was instructing local offices to pay special attention to the filling of vacancies in this work. An advisory committee had now been formed, under the chairmanship of Mr. McCorquodale, and had held its first meeting. [This Standing Advisory Committee on Institutional Domestic Employment includes one medical member—Dr. F. Hall, County Medical Officer of Health, Lancashire.]

#### Availability of Quinine in Bengal

Sir ARCHIBALD SOUTHBY inquired on Dec. 20 whether adequate stocks of quinine existed in Bengal, and whether it was possible for the public to buy quinine.

Mr. AMERY replied that large quantities of quinine had throughout been available to the Government of Bengal, but until the middle of November the arrangements for its distribution inside the Province were unsatisfactory. These had been improved. Distribution in the famine areas was mainly free through hospitals, doctors, and the military relief organization. Sale to the public was controlled at Rs. 37 per lb., but local shortages had driven trade stocks underground and black market prices were much higher.

#### Decisions of Medical Boards

On Jan. 25 Mr. TOMLINSON, replying to Mr. Kirby, said that there was no provision for appeals against the decisions of medical boards. If, however, medical evidence was produced which suggested that there was some room for doubt regarding the correctness of a man's grading, the case was considered by a medical officer of the Ministry of Labour, and where appropriate the man was re-examined. Moreover, men directed to enrol in the Home Guard had a statutory right to appeal against the direction to a local appeal board, which, if of opinion that the man should be medically re-examined, must recommend withdrawal of the direction with a view to such re-examination.

#### Typhus in Naples

Sir JAMES GRIGG on Jan. 25 informed Mr. G. Strauss that the typhus epidemic in Naples was confined to the civilian population, among whom the incidence had steadily increased since the summer. Control of the epidemic was in the hands of the Deputy Chief Civil Affairs Officer and the United States Typhus Commission. Mass disinfection and the inoculation of key personnel had been organized.

#### The Nation's Milk Distribution

In the House of Commons on Jan. 25 Colonel LLEWELIN made an explanatory statement on the new Defence Regulation G, which imposes restrictions on the sale of raw milk in certain areas. He said that the policy of the Government on measures to improve the quality of the nation's milk supply was set out in a White Paper published last July. This regulation carried out that policy in so far as it was concerned with the control of the classes of milk sold in certain areas. The need for this control was fully explained in the White Paper. The regulation prohibited the sale of milk by retail in areas to be specified in Orders to be made by him unless it was T.T. milk and, in Scotland, certified milk; accredited milk and, in Scotland, standard milk, so long as in both these cases they were derived from a single herd; or heat-treated, pasteurized, or sterilized milk. The areas which would be specified were those in which a rationalization scheme was in force for economizing the use of men and vehicles, and thereby having the effect of restricting consumers in the choice of their dairymen. No area would be specified until he was satisfied that facilities existed for supplying adequate quantities of heat-treated milk to meet the requirements of the area.

*Mental Hospitals in Scotland.*—On Jan. 18 Major LLOYD asked the Secretary of State for Scotland whether he was aware that the status and administration of the Royal mental hospitals were not considered by the Hetherington Committee, although these hospitals

were an integral part of the health services in Scotland. Mr. JOHNSTON said he was informed that, in refraining from making recommendations based on the evidence which they received on the subject of the Royal mental hospitals, the committee had in mind that the mental hospital service rested on a special code of law which was at present being reviewed by the Russell Committee on the Lunacy and Mental Deficiency Laws of Scotland. The position of the Royal mental hospitals in relation to the proposed new health service was not being overlooked.

*Diet of Miners.*—Sir E. GRAHAM-LITTLE on Jan. 18 asked the Minister of Food whether he would institute an inquiry into the diet of miners and other sections of the community engaged in hard physical labour, as there was evidence that a deficiency in energy-producing items of diet accounted for much of the absenteeism now impeding the production of coal and other vital war efforts. Mr. MABANE replied that the nutritional requirements of every class of consumer were under constant review by his Department, and special attention was now being given to the needs of the types of workers referred to.

## The Services

The *London Gazette* has announced the award of the M.C. to Fl. Lieut. R. J. L. Ferris, R.A.F. The announcement reads as follows:

Fl. Lieut. Ferris, the medical officer of No. 74 Squadron, has displayed outstanding gallantry and devotion to duty. During a period in October, 1943, his headquarters was subjected to severe enemy air attacks. On one occasion four men were killed and two others were buried under the debris. Fl. Lieut. Ferris immediately set to work removing the bodies and releasing the buried men. His medical equipment had been destroyed and he was compelled to work with a pair of scissors and a small wood-saw, with which he succeeded in releasing one man after amputating his leg. Fl. Lieut. Ferris accomplished this while the air attack was in progress and worked with very little light and while held upside down by his legs. During an engagement between British and enemy ground forces he treated military and civilian casualties alike. Fl. Lieut. Ferris worked incessantly under most rigorous conditions. His coolness and courage proved a source of inspiration to all.

The Efficiency Decoration has been conferred upon the following officers of the Territorial Army: Col. H. A. B. White Locke, late R.A.M.C.; Lieut.-Col. (temp. Col.) W. H. Marston; Lieut.-Cols. T. F. Arnott, O.B.E., and S. J. Hartfall; Majors (temp. Lieut.-Cols.) J. A. Bruce and F. Heywood-Jones; and Majors H. W. Davies, L. F. Jefferoot (T.A.R.O.), C. R. L'E. Orme, and L. F. Richmond, R.A.M.C.

The following have been mentioned in dispatches by Air Officers Commanding-in-Chief:

Gp. Capt. J. K. R. Landells; Gp. Cpts. (Acting) A. Harvey, C. J. S. O'Malley; Wing Cmdrs. T. J. X. Canton, L. E. A. Dearberg, G. A. M. Knight, J. W. Patrick, C. E. G. Wickham; Wing Cdrs. (Acting) H. H. S. Brown, R. C. Jackson, J. H. L. Newnham; Wing Cmdr. (Acting) E. B. Harvey, R.A.F.O.; Squad. Ldrs. W. Hargrave-Wilson, A. L. Knipe, M. L. Maley, S. Rogers, A. S. Simpson, D. Turner, J. L. W. Walls, R.A.F.V.R.; Squad. Ldrs. (Acting) B. J. Bickford, E. R. Brown, I. W. H. R. Cran, C. F. Hamilton-Turner, W. L. Hector, R. N. Houlding, D. A. Ker, H. J. Little, P. J. O'Connor, J. E. Smith, D. Stafford-Clark, M. W. L. White, R.A.F.V.R.; Fl. Lieuts. T. G. Band, A. J. Chiappa-Sinclair, P. J. Bryce-Curtis, R. C. Dickson, R. E. Glennie, C. M. Liddell, A. D. MacLean, A. F. Pearson, T. Primrose, O. H. Sennett, J. A. Sutton, H. M. Urquhart, R.A.F.V.R.; Squad. Officer (Acting) A. L. J. Dovey, W.A.A.F.

#### CASUALTIES IN THE MEDICAL SERVICES

*Killed in action.*—Capt. J. F. V. Lart, R.A.M.C.

*Reported missing.*—Surg. Cmdr. H. de B. Kempthorne, R.N.

*Killed.*—War Subs. Capt. D. W. Forgan, R.A.M.C.

## Universities and Colleges

#### UNIVERSITY OF EDINBURGH

At a graduation ceremonial on Jan. 22 the following medical degrees were conferred:

M.D.—T. G. Brown, Christina M'D. Taggart.  
Ph.D.—(In the Faculty of Medicine): F. Alexander.  
M.B., Ch.B.—P. Aitken, \*C. A. Barrett, E. Bindman, T. F. Boyle, D. Cameron, J. A. Campbell, T. I. Cleithon, T. G. Crombie, A. W. Cunningham, J. N. Dobson, T. E. Donaldson, K. Drummond, W. A. Eagles, J. T. Kin, W. H. Elliott, S. J. Evans, J. W. Farquhar, D. H. Forster, G. F. Hawkins, A. G. Henderson, D. W. D. Hendry, J. M. Herd, J. M. Kerr, D. K. Kouyoumdjian, C. E. Lim, I. W. F. Lumsden, H. F. Low, \*R. J. M. McCormack, G. D. McDonald, A. H. McEerrow, R. S. McNeil, J. H. Macpherson, D. MacVicar, J. D. Malloch, J. S. Milne, J. F. G. Mitchell, R. G. Mitchell, T. R. Nelson, J. A. Paterson, R. M'C. Paterson, R. G. Pinkerton, R. R. Pratt, K. Rhaney, \*I. M. Richardson, Jessie R. Robinson (née M'Laren), G. J. Romanes, R. S. Ross, J. T. R. Russell, Isabella M. Scott, J. H. Scott, B. M. L. Shields, E. S. Shoucair, Catherine M. G. Smith, Margaret S. Stevenson, R. C. F. Todman, \*P. R. Walbaum, J. H. Walmsley, I. Wang, Elizabeth Whalley, W. E. J. Wilson, G. D. Wright.

\*With honours

## EPIDEMIOLOGICAL NOTES

## Discussion of Table

In England and Wales during the week the notifications of whooping-cough rose by 220, but those of acute pneumonia dropped by 314. There were 44 fewer cases of scarlet fever and 28 fewer of cerebrospinal fever. Notifications of measles went up by 44.

There were 197 deaths from influenza in the great towns, a fall of 58. For the week ending Jan. 22 the influenza deaths numbered 143. Almost one-third, 61 deaths, were recorded in the Greater London area, although only 19 were registered in the administrative county of London.

The only large variation in the county totals for whooping-cough was an increase in Essex of 40. The lower incidence of scarlet fever was due to the northern counties; in the south there was a tendency to a higher incidence. The only feature of note in the trend of measles was the small but continuous rise in London from 36 to 98 in the past three weeks. The decline in the notifications of pneumonia was general throughout the country, except in the north midland region, where there was a slight rise.

Dysentery notifications were 10 more than in the preceding week. The largest returns were London 34, Kingston 18; Lancashire 38, Manchester C.B. 29; Sussex 27, Chichester R.D. 14, Bognor Regis U.D. 9; Essex 13, Rochford R.D. 10.

In Scotland notifications of measles and whooping-cough rose respectively from 43 to 207 and from 121 to 252. Notifications of acute primary pneumonia dropped by 159 and those of diphtheria by 21. The rise in measles was due to two towns, Glasgow and Paisley, where increases of 104 and 59 were recorded. Glasgow, with a rise of 108, was the only centre with a large increase in the notifications of whooping-cough. One case of typhus was reported from Ayr county.

In Eire there was a decline in most infectious diseases, but the incidence remained unchanged in Dublin C.B.; 85% of the total notifications of measles, one-half of whooping-cough, and more than one-quarter of diphtheria were reported in this city.

In Northern Ireland the notifications of diphtheria rose from 32 to 51.

## Week Ending January 22

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,110, whooping-cough 2,215, diphtheria 712, measles 661, acute pneumonia 1,122, cerebrospinal fever 70, dysentery 148, paratyphoid 2, typhoid 2. Influenza deaths in the great towns numbered 143.

## Points from Abroad

The epidemic of typhus in Naples, which has so far been confined to civilians, has reached such proportions that it constitutes a potential menace to the military effort in Italy. A six-point programme has been put into operation by the American Typhus Commission. Disinfection stations have been established, where as many as 70,000 civilians are treated each day. A vigorous search has been made for all possible cases. Immunization by serum has been organized. The outbreak began under German occupation, and has increased as a result of overcrowding and lack of adequate facilities to deal with the thousands of refugees, and of the demolition of the water and gas supplies by the Germans.

It is reported from Berlin that the incidence of stillbirths has risen from 2.8% in 1942 to 5.1% in 1943.

The following figures are quoted from *Wirtschaft und Statistik*. The number of births in 1943 was 995,744 in Germany and the incorporated territories. Deaths (civilians only) amounted to 725,257. There were 42,000 fewer children born than in 1942. In the period 1940-3 the deficit of births compared with the position in 1939 was 892,000, whereas in the years 1915-18 it was roughly 3,000,000. There were 20,700 fewer deaths among the civilian population in Germany than in 1942.

It is reported from Berne that in France the high mortality of children constitutes a difficult problem for the Vichy Government. The number of deaths exceeded the number of births in 1942 by 93,626, as compared with 55,758 in 1938.

According to statistics compiled by Dr. Veld, Medical Inspector for National Health in South Holland, the number of diphtheria cases confirmed in 1938, 1939, 1940, 1941, and 1942 amounted to 1,272, 1,273, 1,732, 5,452, and 19,417 respectively. In 1943 up to and including Oct. 31 there were 40,336 cases.

No. 2  
INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 15.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable; or no return available.

Disease	1944					1943 (Corresponding Week)

<sup>1</sup> Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

<sup>2</sup> Includes puerperal fever for England and Wales and Eire.

<sup>3</sup> Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

# Medical News

The British Association of Physical Medicine is meeting at 11, Chandos Street, London, W.1, to-day, Saturday, Feb. 5, at 2.30 p.m., to discuss the objects of the Association under the heading "The Place of Physical Medicine in Teaching and in Practice." Several short papers will be read before the discussion takes place.

A meeting of the Clinical Society of the Royal Eye Hospital will be held at the hospital, St. George's Circus, Southwark, S.E.1, on Friday, Feb. 18, at 4.30 p.m., when a talk will be given by Dr. Francis E. Preston on "Ophthalmic Prescribing and Therapeutics."

A meeting of the London Association of the Medical Women's Federation will be held in the Common Room of B.M.A. House on Saturday, Feb. 19, at 3 p.m., when Miss Jean Dollar, F.R.C.S., D.O.M.S., will speak on sulphonamides in ophthalmology.

A Chadwick Public Lecture will be given on Tuesday, Feb. 22, at 2.30 p.m., at the Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W., by Mr. C. E. A. Bedwell on "The Place of the Hospital in the Health Service." The lectures for the spring programme, 1944, will deal generally with public health matters and the war. Admission is free.

The meeting of the Nutrition Panel of the Society of Chemical Industry will be held at Burlington House, Piccadilly, W., and not at 56, Victoria Street, Westminster, S.W., as stated in the issue of Jan. 29 (p. 169).

It is announced that Prof. H. W. Florey, F.R.S., has left England for Russia to pass on to Soviet doctors his knowledge of penicillin as a therapeutic agent. Prof. Florey returned recently from the Middle East to present to the War Office and the Medical Research Council a detailed report on the use of penicillin in war wounds. (See *Journal*, Dec. 11, 1943, pp. 750 and 755.)

A Turkish medical mission has arrived in this country to study medicine and surgery in wartime, under the auspices of the British Council. Its members have been nominated by the Turkish Ministry of Health. Dr. Hüseyin Avni Aksef has for the past 10 years worked at the Haseki Hospital, Istanbul, where he is now chief surgeon, and has lately taken special interest in surgery of the lung. Prof. Burhanettin Tugan was appointed in 1928 professor of clinical chemistry at the Gülhane Military Medical School, and still holds that post. As a lieutenant-colonel in the Turkish Army he is a member of the Military Medical Academy, and he is also a member of the Turkish Medical Council. He represented Turkey at the 9th and 10th International Congresses of Military Medicine. Dr. Bekir Nimetullah Taskiran was chief assistant in the surgical clinic of the Faculty of Medicine, Istanbul, and has just been appointed chief surgeon at the Ankara Model Hospital. A small reception was given in their honour.

## Intestinal Flatulence

**Q.**—What are the causes of intestinal flatulence, offensive and inoffensive, but such as to give rise to abdominal discomfort? I can find no authoritative analysis of the gases produced in the intestine. What are they? Where such production is excessive what medicinal and dietetic measures should be taken to remedy the state of affairs?

**A.**—The commonest cause of intestinal flatulence is intestinal carbohydrate dyspepsia. Starch in its natural cellulose envelope is insufficiently digested in the small intestine and consequently undergoes fermentation in the colon. The gases produced—mainly carbon dioxide and methane—are odourless, but may cause much discomfort by the distension they cause. In severe cases the organic acids produced irritate the colon sufficiently to cause diarrhoea. The flatulence can be overcome by a diet containing no starch in its natural form—i.e., no potatoes or other root vegetables, and no rice, sago, or tapioca. Bread and puddings made from prepared starch are allowed in moderation, and there is no need to restrict sugar.

Much less often flatulence results from putrefaction of proteins which have escaped digestion in the small intestine. The quantity of gas produced is comparatively small, but it is very offensive. Diarrhoea is often present. The commonest cause is excessive indulgence in purgatives, and it may even result from taking too much paraffin. It does not result from deficient peptic digestion in achlorhydria, but is a common result of the deficient secretion of trypsin caused by carcinoma of the pancreas. In the absence of the latter the production of offensive gas can generally be prevented by avoiding aperients. In any case a dessertspoonful of powdered charcoal three times a day will deodorize offensive intestinal evacuations.

## Enuresis in Childhood and Adolescence

**Q.**—What investigations are necessary to discover the causes of enuresis, and what treatments might be tried before sending the child to join the child guidance waiting list.

**Q.**—A boy of 17 has been troubled with enuresis for years. Atropine, belladonna, etc., have no curative effect. Would complete hypnotic treatment be likely to cure, and how long would a course take? At present the boy and a younger brother have a bedroom to themselves in a "public school," but he may be leaving school in a few months, and he fears this trouble being a handicap to him in life. The profession, I was told, object to hypnotic treatment (and the school doctor refused to try it, trusting to time as a cure). Why this objection? It seems to me unreasonable.

**A.**—Habitual enuresis, apart from rare instances in which organic factors can be discovered, is a psychogenic disorder. The organic factors to be excluded are: disease of the urinary tract; disease of the C.N.S., especially nocturnal epilepsy, petit mal, and spina bifida; diabetes mellitus and insipidus. Severe mental defect must also be listed.

This done, attention must be focused on the psychological background of the patient—usually a child. Enuresis, like other psychoneurotic symptoms, is an expression of mental protest. It means usually the unconscious assertion or reassertion of claims to irresponsible babyhood. Such a lapse into infantile modes of behaviour is most frequently due to lack of the sense of security in the child's relationships with its world. This may be caused by illness; by negligent, spoiling, or nervous parents, too unsure of themselves to apply healthy discipline and to encourage development towards maturity, or else making too severe demands. In such cases enuresis is a symptom of persistent dependence, and in a sense a due reward of the parental attitude. More often, however, enuresis appears, after a period of normal control, when the child's sense of security is threatened by a change in its habitual environment. The death of a loved person; the birth of a baby, displacing the patient from accustomed priority; the onset of school life, making extra demands on him, especially if he is intellectually handicapped—are common factors. In wartime the loss of security through evacuation to not always congenial strange foster-parents and through the break-up of the child's familiar world is a typical situation precipitating the regression to loss of bladder control. In the child's mind enuresis may mean aggressive, dependent, or self-gratifying impulses—most likely all three. The vicious circle is completed through guilt and inferiority feelings.

Investigations into the history and present conditions of the child's emotional development are therefore necessary. Much can be done by the understanding doctor with time to spare for a long exploratory talk with the parents, school teachers, etc., as well as with the patient. In brief, treatment must aim at eliminating causes for feeling unloved, wanting to see safety; at removal of guilt feelings and discouragement, and at the reward of progress in control. There is no sense in giving medicine or prescribing fluid-intake regimes, as these further cloud the issue and make the child and its guardians take a wrong view of the condition. Many cases may respond quickly to quite simple encouragement and interest in helping them. For the rest, the child

## Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES—EDITOR, *Attilology* Westcent, London; SECRETARY, *Medicera* Westcent, London. ADVERTISEMENTS, *Articulate* Westcent, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshough Gardens, Edinburgh.

## ANY QUESTIONS?

### Degeneration of Pyramidal Tract

**Q.**—A man aged 60 years, who has suffered for many years from a familial form of degeneration of the pyramidal tract, at first thought to be a primary lateral sclerosis, has for the last ten years suffered from rheumatoid pains in joints and muscles. These pains are at times very severe and disabling. Ordinary analgesics are useless. Is any form of light treatment likely to be of use, or drugs?

**A.**—The data are insufficient to form an opinion in this case; it is not clear what is meant by "rheumatoid" pains in joints and muscles. It would seem probable that the pains originate in the spinal centres unless there are local changes. It is very unlikely that any form of light treatment would help. Short-wave diathermy in skilled hands would be worth a trial, but haphazard application would be futile. The only drugs likely to be of service are analgesics. Has pehidine been tried? Potassium iodide might also be indicated.

guidance clinic, with or without waiting list, exists to cope with the quite involved social problems such cases sometimes present, in which the child is but a pawn demanding consideration through nuisance value.

The inquirer's attention is drawn to the relevant and wise letter by Dr. Herbert W. Bland in the *Journal* of Jan. 15 (p. 93).

The school doctor in the second case was probably wise to refuse to "try hypnosis." Objection to hypnosis springs from two rather different motives. One is an unreasoned prejudice against this method altogether; the other is an informed assessment of its value in this type of case. Most of what has been said above in regard to causation holds good also for the stresses of adolescence. Hypnotic suggestion in the hands of the trained psychiatrist may possibly be the final method of choice. But it must be preceded by diagnosis of the conflicts and maladjustments of the patient, of which enuresis is the outward and visible sign. The school doctor's objection, on the face of it, might have been based on the first of these objections, his optimism with regard to "time as a cure" is not often borne out by the after-history, and he suggested nothing positive. The case would seem to be eminently suitable for investigation by an "expert," as otherwise the patient's own fears may indeed be justified. Psychopathology has reached a stage of development when blind empiricism in therapy is as little justified here as in any other branch of medicine. The tempting use of the magic of hypnosis will not necessarily have done anything to alter the balance of mental forces of which the enuresis was the outcome, and which, rather than the symptom, is the essence of the patient's disability. The reasonable objection to the employment of hypnosis is, therefore, analogous to our preference for finding out why somebody is weeping rather than for plugging his lacrimal ducts.

#### Rectal Paraldehyde during Labour

**Q.**—Further to your reply to the question on analgesia in labour in the *JOURNAL* of Jan. 1, p. 30, I should be glad to have details of the technique of the administration of rectal paraldehyde during labour and to know what risks are associated with this treatment.

**A.**—A safe maximum dosage is based on 1 drachm of paraldehyde per stone of body weight. In actual practice 6 drachms of paraldehyde gives good results in all but the biggest and heaviest patients. It is conveniently made up in 4 oz. of saline or olive oil when this is procurable. Following the administration of an enema early in the first stage the paraldehyde is slowly injected into the rectum, preferably taking 10 to 15 minutes over the process. It is an excellent basal anaesthetic, is not associated with any risk to either the patient or the child, the only danger being over-dosage—namely, giving ounces instead of drachms. For this reason a careful check is essential before the administration of the drug. Cases in which the vertex is deep in the pelvis a soft catheter would be inserted per rectum above the level of the head. Otherwise the paraldehyde is liable to be returned.

#### Tonic Action of Strychnine

**Q.**—I should welcome an authoritative statement on the action of strychnine as administered in ordinary therapeutic doses. (1) Do the ordinary iuxta-ventricular nuxtures have any "tonic" action in, for example, cases of post-influenza debility, or is the action of such nuxtures little more than that of a stomachic? (2) What are the older views on the value of strychnine as an emergency injection such conditions as pneumonia and heart failure?

**A.**—1. Strychnine in ordinary therapeutic doses undoubtedly has tonic actions apart from its action as a stomachic. It can be shown, for example, that it causes a measurable increase in the field of vision, and there is no reason to doubt its value as a general tonic. 2. Strychnine is not of much value in an emergency. It does not stimulate the heart, and acts on the respiratory and vasomotor centres only when given in convulsive doses. Other drugs, such as nikethamide or leptazol, have more action on these centres and may thus indirectly revive a failing heart.

#### Marginal Gingivitis in School Children

**Q.**—What advice or treatment should be given for the minor degrees of marginal gingivitis so commonly seen in school children? Some cases it is associated with, in others independent of, regularity. The worst degrees are commonly in the upper or lower incisor region.

**A.**—Any state of ill-health or lowered resistance will increase a liability to a marginal gingivitis, but the local factor is a stagnation of saliva and food debris. It is essential, therefore, that in the treatment of the condition inquiries should be made into the life of the child and stress laid on the absolute necessity for proper "tooth-brush drill." The teeth and gum margins must be cleaned night and morning, after every meal, and indeed after every drink or glass of milk. Mouth washes help, and chewing gum, procurable, is excellent as it not only cleanses and massages the gums but stimulates the flow of saliva and reduces the craving for sticky sweets. A common-sense routine will clear up almost every

mild case in a few days, but attention must also be paid to any tendency to mouth-breathing, especially during sleep, which is probably the commonest cause of an anterior gingivitis. The aid of the dental surgeon must be sought if any tender tooth is present, causing the child to masticate on only one side of the mouth. Any overcrowding of the mouth is better treated by judicious extractions than by any form of orthodontic appliance. Local treatment, when necessary, will be undertaken by the dentist, but the doctor should satisfy himself that the proper hygiene is carried out at home and that the child has no deficiency in vitamins.

#### Transport of Cases of Fractured Spine

**Q.**—There seem to be conflicting opinions about the first-aid measures to be adopted in suspected cases of fractured spine. How, for example, should a man found lying prone in the street be moved on to a stretcher if thought (a) to have a broken neck, and (b) to have a broken back? An authoritative answer to this question would assist many G.P.s who are now giving lectures on first aid.

**A.**—Patients with suspected spinal fractures should be shifted and moved in such a way as not to be folded either backwards or forwards. The patient should be disturbed as little as possible, being transported "as he lies." From the point of view of the spinal injury, no matter at what level, there is no indication for change of position from face to back or vice versa.

#### Hereditary Factor in Psoriasis

**Q.**—What part does heredity play in psoriasis? My experience has been that it does not play as important a part as textbooks would lead one to believe. What are the possibilities of the condition being transmitted if it only develops in early adult life as isolated patches on the scalp, apart from one small chronic patch on the leg since childhood?

**A.**—There would seem to be no doubt that psoriasis is transmissible from one generation to another, and that it may occur in several members of a family. Cockayne in his monograph, *Inherited Abnormalities of the Skin*, comments upon the paucity of the published pedigrees. Expressed in percentages the family incidence as recorded by various observers, quoted by Cockayne, varies from 15 to as high as 63%. This second figure hardly accords with the experience of dermatologists in Great Britain. The chance of transmission is unlikely to be modified because the disease has developed in early adult life and in a limited form.

#### Treatment of Leucorrhoea

**Q.**—What is the treatment of leucorrhoea, often met with in school-girls, especially of the poorer classes?

**A.**—Leucorrhoea is taken to mean an increase in the normal discharges and not a purulent discharge due to infection. Such an increase at puberty is physiological and temporary; tending to resolve spontaneously. Apart from this, troublesome leucorrhoea in young girls is usually associated with general debility (as after serious illness), malnutrition, lack of cleanliness, sedentary habits, and constipation. Occasionally an erosion of the cervix may be the cause. Treatment should therefore be on general lines—attention to cleanliness, regular exercise out of doors, adequate diet, general tonics, haematinics if there is anaemia. Saline aperients and daily cold baths or contrast baths may help.

Local treatment should be avoided if possible in young girls. As a last resort, astringent douches such as 1% alum can be used, or an erosion of the cervix cauterized.

#### Quality of Breast Milk

**Q.**—Can breast milk be deficient in quality while sufficient in quantity in a healthy mother? This question is prompted by the case of a healthy mother with apparently ample milk and a healthy baby of six weeks who appears to be satisfied with the volume of breast milk after bringing up wind, and yet in 1 to 2 hours wakes up hungry. After a feed of dried milk he rests satisfactorily. His stools are normal usually, but sometimes curdy, and he is gaining weight at the normal rate.

**A.**—Minor qualitative variations can of course occur. A mother on a deficient diet probably cannot produce an adequate amount of vitamins in the milk. But as regards the caloric value it is doubtful if this varies much. Workers in India have described how mothers dying of starvation have nevertheless fed babies at the breast who gained in weight. So the obvious deduction from the question is that the child is not getting enough to eat. "Ample milk" is too loose a phrase. Test feeding would settle what was the daily quantity available, but even then the exact requirements of the baby cannot be calculated. A common-sense deduction from the facts as stated is either that the baby is underfed or that he is overfed, getting a pain in his abdomen 1 to 2 hours after a feed which is relieved by a warm feed. If he is gaining weight at the normal rate with the dried milk feed in addition, it suggests that he is actually underfed at the breast.

## Influenza Immunization

Q.—Is it possible to produce active immunity towards epidemic influenza? Is it best to use a "virus suspension" or a vaccine?

A.—Epidemic influenza is a virus disease, and the reagent used for active immunization must therefore be a preparation of virus. Such virus vaccines, usually in the form of infected monse-lung suspensions, have been shown to raise the specific antibody content of the blood, but in field trials the method has on the whole given disappointing results in the prevention of the disease. Reasons for this are not far to seek, and two of them are of such weight that it is difficult to see how any considerable improvement on the present position is likely to be achieved. These are:

1. For such immunization to be regularly successful the disease must be caused by a single organism of constant antigenic composition, as in the case of typhoid fever. In influenza this is not so; it has at least three causes: two antigenically different viruses known as A and B, while in some further cases, since neither of these viruses is found, a third agent must be responsible.

2. The immunity produced by a natural attack of the disease may be short-lived: there are well-attested cases in which two attacks due to virus A have occurred in the same season. If the disease itself sometimes immunizes so incompletely, what can be expected of an artificial method?

If the word "vaccine" in the question refers to a bacterial vaccine, the answer is that this can protect only against that form of influenza, if it exists, which has a bacterial cause, or against complications. "Anticatarrh" and "anti-influenza" vaccines usually contain five or six species of bacteria, some of which possess many antigenically distinct types (pneumococcus and *Str. pyogenes*, which have been better studied than the remainder, include about 30 each), and the degree of specific immunity so obtainable against any one organism must be very small. The theoretical unsoundness of this proceeding has a counterpart in the results of carefully controlled trials, which have failed to show that any protection is conferred.

## C. diphtheriae in the Vagina

Q.—What is the treatment for vaginal discharge in a girl of 6 years swabs from which are positive for the Klebs-Loeffler bacillus found to be virulent on animal inoculation? The condition has persisted for over three months. The child was immunized at the age of 4 by two doses of A.P.T. Treatment so far tried has been: (1) reinforcing dose of 0.5 c.cm. A.P.T.; (2) 10,000 units anti-diphtheria serum; (3) painting the vulva daily with antidipltheria serum; (4) daily baths and swabbing with mild disinfectant. The general condition of the child is very good.

A.—In view of the obvious difficulty of thorough local examination I would suggest first that the presence of virulent diphtheria bacilli now should be confirmed. Diphtheroids of various kinds are not uncommon in the unhealthy vagina, and the original virulent bacilli may have been replaced by a harmless relative. If this is established it is imperative to ensure that the child is Schick-negative. This could reasonably be assumed, but the point should be rechecked, and if she is positive she should be at once given diphtheria prophylactic, preferably A.P.T. Also, the people endangered by direct contact should be Schick-tested and, if positive, protected by immunization. If true diphtheria bacilli are present and the child is Schick-negative, probably toxin from the bacilli plays virtually no part and the bacilli are flourishing "extracorporeally," as in the case of a Schick-negative child carrying virulent bacilli in nasal mucus. It follows that further active immunization, or antitoxin locally or elsewhere, is not called for. Careful local examination by a gynaecologist may reveal some unhealthy focus—e.g., an infected gland or even an endocervicitis where the bacilli harbour and from which they must be routed by appropriate local treatment (in which sulphathiazole powder might play a part). Is trichomonas present?

## INCOME TAX

## Annual Payment under Covenant

E. F. makes annual payments of £240 a year to his step-sister under a covenant, the terms of which are not such as to be void for income-tax purposes. What is the method of obtaining relief?

A.—What E. F. has done in effect is to transfer £240 of his income to his step-sister. He should deduct tax at 10s. in the £ from each payment made on account of the annuity. That will give him the relief due to him, but, of course, he must account to the Revenue for the tax so deducted and retained by him. He must accordingly pay tax at 10s. in the £ on £240 of his income, which means that he will have to forgo the earned income relief on such grant of his earnings as have to be used to make up the £240 a year. The step-sister, of course, claims repayment of such part of the tax as may be necessary to give her the allowances she is entitled to—i.e., on £80 personal allowance, £50 child allowance, and at 3s. 6d. in the £ on the balance of £110.

## LETTERS, NOTES, ETC.

## Umbilical Hernia

Dr. ANN MOWER WHITE (S.E.17) writes: In your reply on umbilical hernia (*Journal*, Dec. 11, p. 771) I was a little surprised to read that "most of these cases, however, can be satisfactorily treated if from the earliest days any attempt at protrusion of the umbilical stump is overcome by padding a penny and using it as a splint. It can be kept in place by adhesive tape or a binder." As this recommendation is contrary to modern practice, I venture to quote from *Clinical Paediatrics*, by Morse (p. 83). "It is useless to try to prevent or cure an umbilical hernia with a pad and tight flannel binder. . . . The best treatment is with a plaster strap. It should be two inches in width; the hernia should be pushed in and then the skin on each side of the navel folded in to act as a splint. The strap should then be applied. . . . It is not advisable to use a coin or button over the navel, under the strap, because although the coin or button may prevent the hernia coming out, it does not favour the closing of the ring in the way the folding of the skin does." Holt and Howland in *Diseases of Infancy and Childhood* (p. 93) also state: ". . . the skin along the line being folded inward so as to overlap the tumour, thus forming a retention pad." From my personal experience I can say that I have treated many hundreds of cases in this way with satisfactory results.

## Treatment of Leukaemia

Dr. A. PINEY (London, W.1) writes: The answer to the question about the treatment of leukaemia in the *Journal* of Jan. 22, p. 137, is both incomplete and misleading. Irradiation is not the only method of treating this disease; arsenic is of at least equal value, and in the early stages offers several advantages. Thus, in leukaemia, every therapeutic weapon becomes blunted sooner or later, and it is therefore best to start treatment with the mildest agent; later, irradiation can still be used, but arsenical treatment does little good to patients who have already been irradiated. Arsenic properly administered will reduce the leucocyte count, cause diminution in the size of the spleen, and, in febrile cases, will control the fever. Personal experience has amply demonstrated these facts, but for those who prefer the printed word I would call attention to the paper by E. V. Kandel and D. V. Leroy (*Arch. intern. Med.*, 1937, 60, 846) and to the monograph by C. E. Forkner (1938). The treatment of the leukaemias has passed almost entirely into the hands of radiologists, much to the detriment of the sufferers. The time to start treatment is when there is deterioration in the blood picture and some clinical evidence of increased ill-health. I do not deny that radiologists, entrusted with the treatment of a case of chronic leukaemia, rapidly increase the patient's efficiency. But I do assert that a skilfully treated patient—i.e., one whose treatment is planned according to the stage of the disease—will feel as well and will live a good deal longer.

## Infant Feeding

Dr. CATHERINE JAMES (Burgess Hill) writes: I was interested to read the case reported by Dr. Patria Gairdner (*Jan. 8, p. 44*). One does not know whether to be more surprised at the heroic measures adopted or at the infant's vitality in surviving it all, but one short tragic phrase at the very outset clearly shows that the whole illness could have been avoided. We read that the breast feeds of this infant before it was a week old were "complemented with national dried milk." Not long ago a case was reported in your columns of a baby weaned at the third day "because there was no breast milk." When will doctors learn not to interfere with the establishment of the only safe natural method of infant feeding? I should say that only in very exceptional cases should a baby ever be weaned or receive complementary food under the age of six weeks, even if it is losing weight. The vast majority will find, as this unfortunate infant did, that "mother's milk is coming better" in three or four weeks. I write in the hope that other infants may be spared the tragic sequence—overfeeding, diarrhoea, dehydration, intravenous drip, thrombophlebitis, pyopneumothorax. I note too, the sound common sense of this child, who from Feb. 1 "resolutely refused bottle feeds; within 24 hours she was for the first time entirely breast-fed. From that time she never looked back."

Dr. ETHEL EMSLIE (London, W.9) writes: The Ministry of Health report on breast-feeding has omitted one detail which, I think, is of importance in the encouragement of breast-feeding. The mother should be told to assume a comfortable position leaning back in a chair with the infant held well up, not flat, in the hollow of her arm. In this position the baby swallows less air, and the mother obtains two and a half or three hours' rest daily. At the present time mothers appear to be taught in hospitals to sit crouched over the babies lying almost flat on their laps. This is very tiring indeed for the mother, especially if she has little chance of resting at any other time, but it appears to be a universal practice. May I put in a plea for giving complementary feeds, when they are necessary, from a spoon, not a bottle?

LONDON SATURDAY FEBRUARY 12 1944

## STUDIES ON HEPATIC DYSFUNCTION

### I. CARBON TETRACHLORIDE POISONING TREATED WITH CASEIN DIGEST AND METHIONINE

BY

J. BEATTIE, M.D., D.Sc.

*Bernhard Baron Research Professor, Royal College of Surgeons of England*

P. H. HERBERT, B.A.

*Leverhulme Scholar, Royal College of Surgeons of England*

C. WECHTEL, M.D.

*Capt., U.S. Army Medical Corps*

AND

C. W. STEELE, M.D.

*Major, U.S. Army Medical Corps*

(From a U.S. Military Hospital, E.T.O., and the Bernhard Baron Research Laboratories, Royal College of Surgeons of England)

The interest of the case recorded below lies in the successful use of a method of treatment not hitherto applied to man. It was felt that the following considerations, which seemed to indicate a probably fatal outcome, justified its adoption: (1) The large quantity of carbon tetrachloride alleged to have been swallowed—30 to 40 ml. The maximum therapeutic dose is 4 ml., but fatalities have been reported with doses as low as 1.5 ml. (2) The probably complete absorption of the drug. Immediate symptoms indicated a rapid entry into the circulation. Vomiting was not induced until 45 minutes after ingestion. (3) The speed with which the liver enlarged. (4) The delay of 19 hours between the accident and the institution of treatment.

#### Case History

An Army Air Force sergeant-pilot (white) aged 23 ingested by mistake "two large swallows" of carbon tetrachloride at 4.15 p.m. on Oct. 2, 1943. The quantity was determined later to be between 30 and 40 ml. No food had been taken since breakfast at 7.15 a.m. The patient noted an immediate "hot burning sensation" in his "throat and stomach." He became rapidly "dizzy and lightheaded," but was able to walk with assistance to the camp infirmary. At 4.35 p.m. he was given large quantities of salt and water by mouth to induce vomiting. This did not occur until 45 minutes after the accident, and was not repeated. The medical officer observed that at this time the patient was confused mentally, and subsequent questioning revealed that there had been a loss of memory of events between his arrival at the camp infirmary and his transfer to hospital at 6.30 p.m. On admission to hospital he was put to bed and given  $\frac{1}{2}$  gr. of luminal to alleviate his apprehension and restlessness. He was still dizzy and nauseated throughout the night, but vomited only once. He refused food on the evening of admission and on the morning of the following day—Oct. 3.

At 11 a.m. on Oct. 3 he came under our observation. One of us (W.) examined the patient, who was restless and complained of dizziness. Jerking movements of the limbs and rolling of the head from side to side were observed. The pharynx was red and injected. Abdominal palpation revealed a tender liver with rounded edge. This edge extended 2 in. below the costal margin in the right anterior axillary line and  $1\frac{1}{2}$  in. below the costal margin in the left anterior axillary line. It was also palpated  $1\frac{1}{2}$  in. above the umbilicus. All these and subsequent measurements were taken during normal respiration, and were confirmed by three observers. No other abnormal signs or symptoms were noted.

At 12.30 p.m. the patient was given 2 g. of *dl*-methionine by mouth. This was retained. At 3.30 p.m. 1 ml. of a casein-digest-methionine solution was injected slowly into an antecubital vein. There was no immediate reaction. Five minutes later 5 ml. was injected, also without reaction. Continuous infusion of the solution by a Murphy drip apparatus was begun immediately. The rate of infusion was about 2 ml. a minute. At 6.30 p.m., when 436 ml. of

the solution had been infused, the patient complained of chilliness, intense headache and backache, and some aching of the limb muscles. The pulse was thin and the lips slightly cyanotic; the blood pressure was 130/20. Infusion was stopped, hot-water bottles and extra blankets were applied, and 5 gr. of an aspirin-cocaine mixture was given. One hour later the colour had improved, the aching had been relieved, and the blood pressure was 120/88. The temperature was 100.8° and pulse 100.

At 6 p.m. it was noted that the liver was still tender and had enlarged considerably. The edge, which was rounded, had reached the level of the umbilicus on the middle line and was between 2½ and 3 in. below the costal margin in the anterior axillary line. At 7 p.m. the patient was given a small meal, which he ate and retained. Nausea, dizziness, headache, and muscle aching had disappeared before 11 p.m. The night was uneventful.

At 9 a.m. on Oct. 4 the patient was mentally alert and made no complaints. Abnormal muscle movements, dizziness, headache, and nausea were absent. The liver was no longer tender on palpation. The edge, which had now become sharp and firm, was half an inch below the costal margin in the right and left anterior axillary lines. He ate all the food placed before him during the day and said his appetite was good. He had a good night.

At 8 a.m. on Oct. 5 he complained that his dizziness and headache had returned. He felt tired and devoid of energy, and his appetite was poor. He was not nauseated and had no abdominal discomfort. The alertness noted on the 4th had been replaced by apathy and listlessness. Questions were answered slowly and with effort. Abdominal palpation revealed that the liver had again enlarged. The edge was rounded, soft, and tender. It was felt one inch below the costal margin in the right anterior axillary line. The spleen was palpable. At 9 a.m. 2 g. of methionine was given by mouth and another 2 g. at 7 p.m. All food presented was eaten. There was no elevation of temperature, pulse, or respiration rate. By 7 p.m. he stated that he felt better. The night was uneventful.

The following morning (Oct. 6) the patient was alert and made no complaints. He said he had a good appetite and expressed a desire to return to duty. Abdominal palpation showed that the liver had again retracted and was palpable about half an inch below the right costal margin on deep inspiration. The liver edge was firm, sharp, and not tender. The spleen could not be palpated.

The patient was retained for observation until Oct. 14, during which time he was symptom-free and received no medication. At no time during the period of observation was icterus noted. The liver was palpable only on deep inspiration during the whole of the period from Oct. 6. He was discharged as fit on Oct. 14 and returned to full duty with his squadron. Between that day and Nov. 2 he was on normal operational flights over enemy-occupied territory. On Nov. 2 he was readmitted for observation. He made no complaints, had an excellent appetite, and said he had been fit since his discharge on Oct. 14. Examination revealed no abnormal signs or symptoms. His liver edge could be palpated only on deep inspiration. It was not tender.

During the period of observation all food given was weighed and its nitrogen and sulphur content estimated from the tables of

McCance and Widdowson (1940). The daily diet contained 100 g. of protein, of which three-quarters was of animal origin. The calorie content of the diet varied between 2,800 and 3,000. The diet was low in fat.

#### Comment on Treatment

Miller and Whipple (1942) showed that fatal liver damage was produced by 30 minutes of chloroform anaesthesia administered to dogs which had been kept on protein-deficient diets for several weeks before. This damage was averted if within 3 to 4 hours after anaesthesia 3 g. of methionine in solution was injected into the circulation. The effect of carbon tetrachloride on the liver is comparable to that produced by chloroform. As our patient was a physically fit young airman whose diet was rich in protein it seemed possible that a massive dose of methionine intravenously might be effective despite the relatively long time which had elapsed since the accident. The small oral dose of methionine (2 g.) was administered pending the preparation of a solution for intravenous infusion.

The infusion was prepared by dissolving 20 g. of a dried papain-trypsin digest of casein in 600 ml. of distilled water. The solution was acidified, and to it was added 15 g. of *dl*-methionine. It was then boiled and filtered. The final pH was 7.6 and the solution was approximately isotonic. It was tested by injecting 20 ml. into the ear vein of a rabbit. No effect was observed within a period of two hours.

The original intention was to administer 15 g. of methionine. This dose was calculated on the basis of 0.25 g. per kg. of body weight, which was approximately the dosage used by Miller and Whipple. In fact, only 9.5 g. was infused, and 2 g. was given by mouth on Oct. 3. Casein digest was added to the solution because it was thought that amino-acids other than methionine might be of some value. As Miller and Whipple had secured good results in their experiments by a single massive dose of methionine it was decided to give no methionine during Oct. 4. The relapse on the 5th, which was treated by giving 4 g. of methionine by mouth, suggested either that our dosage of methionine on the 3rd was too small or that small doses of methionine should have been administered on two or three days after the original massive dose.

The febrile reaction observed in our patient was similar to those reported by other observers (Martin and Thompson, 1943) after infusion of amino-acids. Such reactions are due apparently to too rapid infusion of the amino-acid solutions. It was unfortunate, therefore, that in our patient the rate of infusion was rapid enough to bring on the reaction. A slower infusion might have resulted in the injection of all the solution without reaction, and possibly might have averted the relapse on the 5th.

#### Laboratory Investigations

**Haematology.**—Three blood counts were carried out. The results of these are given in Table I. The raised white count on the 3rd with 74% polymorphonuclear cells was followed three days later by a fall in the white count to 10,500 with a marked rise in the percentage of lymphocytes. There was no significant rise, however, in the total number of lymphocytes. The blood picture almost a month later showed that the lymphocytes had been little affected, and the rise in the white count must be attributed to a rise in the polymorphs. The red cell count calls for no special comment.

TABLE I

Date	R.B.C.	Hb%	W.B.C.	Polymorphs (%)	Lymphocytes (%)	Monocytes (%)	Eosinophils (%)
Oct. 3	5,030,000	100	16,600	74	24	1	1
" 6	5,450,000	—	10,500	53	44	3	—
Nov. 2	5,320,000	100	13,700	61	34	4	1

**Blood Chemistry.**—The various determinations are listed in Table II and commented on later.

**Urine.**—All urine passed after 12 noon on Oct. 3 was collected. Routine tests for albumin, sugar, bile, and urobilinogen were carried out twice daily. Except for the presence of a trace of sugar and a positive urobilinogen reaction in the sample collected between 7 p.m. on the 4th and 7 a.m. on the 5th no abnormality was noted. No acetone bodies were

found in this sample. A few red and white blood cells seen in the sample collected between 3.30 p.m. on Oct. 3 and 7 a.m. on the 4th. No casts were seen in any specimen.

TABLE II

Date	Time	Serum Bilirubin (mg./100 ml.)	Blood N.P.N. (mg./100 ml.)	Blood Amino-N (mg./100 ml.)	Total Cholesterol (mg./100 ml.)	Total Protein (g./100 ml.)	A/G Ratio
Oct. 3	12.30 p.m.	1.10	33	6.4	172	7.3	2.0
" 3	3.30 p.m.	1.30	34	8.7	165	7.5	2.2
" 3	6.30 p.m.	1.90	34	12.7	137	—	—
" 4	6.30 p.m.	0.80	30	5.6	136	7.3	1.9
" 6	8 a.m.	0.88	31	5.2	195	—	—
" 13	8 a.m.	1.00	34	4.9	212	7.4	1.8
Nov. 2	8 a.m.	1.10	39	4.8	197	—	—

The daily urinary output of nitrogen, sulphur, creatinine, and "total creatinine" was estimated. The values obtained are listed in Tables III-VI. The significance of these findings is discussed below.

TABLE III

Date	Urine Vol. (ml.)	Urinary Creatinine (g.)	Total Creatinine (g.)	Total Urinary Nitrogen (g.)
Oct. 3	1,588	1.06	1.12	7.77
" 4	2,730	1.97	2.06	20.64
" 5	1,810	1.55	1.57	12.10
" 6	2,420	1.86	2.08	14.64
" 7	2,210	2.06	2.14	14.78
" 8	2,120	2.01	2.26	14.76
" 9	1,860	2.08	2.10	13.18

The specimen listed for Oct. 3 was collected between 12 noon on that day and 7 a.m. on Oct. 4. All other specimens were from 7 a.m. to 7 a.m., and are listed under the date on which collection started.

TABLE IV.—Nitrogen Balance

Date	Input as Grammes N <sub>2</sub>			Urinary Output (g. N <sub>2</sub> )	Balance
	Food	Methionine and Digest	Total		
Oct. 3	4.8	2.1	6.9	7.8	-0.9
" 4	14.3	—	14.3	20.6	-6.3
" 5	16.4	0.4	16.8	12.1	+4.7
" 6	16.9	—	16.9	14.6	+2.3
" 7	15.7	—	15.7	14.8	+0.9
" 8	16.3	—	16.3	14.8	+1.5
" 9	17.1	—	17.1	13.2	+3.9
	101.5	2.5	104.0	97.9	+6.1

The period listed as Oct. 3 covers the hours between 12 noon on the 3rd and 7 a.m. on the 4th. All other periods are between 7 a.m. and 7 a.m., and are listed as belonging to the day on which collection of urine began.

TABLE V.—Sulphur Balance

Date	Input as Grammes S <sub>2</sub>			Urinary Output (g. S <sub>2</sub> )	Balance
	Food	Methionine and Digest	Total		
Oct. 3	0.33	2.57	2.90	1.00	+1.90
" 4	0.97	—	0.97	2.65	-1.68
" 5	1.09	0.86	1.95	1.01	+0.94
" 6	1.07	—	1.07	1.08	-0.01
" 7	1.01	—	1.01	0.99	+0.02
" 8	1.01	—	1.01	0.97	+0.04
" 9	1.03	—	1.03	0.73	+0.30
	6.51	3.43	9.94	8.43	+1.51

TABLE VI.—Sulphur Partition in Urine

Date	Total S <sub>2</sub> (g.)	Total Sulphate S <sub>2</sub> (g.)	Neutral S <sub>2</sub> (g.)	% Neutral S <sub>2</sub>
Oct. 3	1.00	0.67	0.33	33.0
" 4	2.65	1.30	1.35	51.0
" 5	1.01	0.77	0.24	23.8
" 6	1.08	0.98	0.10	9.3
" 7	0.99	0.91	0.08	8.1
" 8	0.97	0.89	0.08	8.3
" 9	0.73	0.67	0.06	8.2

**Methods.**—Serum bilirubin estimations were carried out by Gibson and Goodrich's (1934) modification of van den Bergh's method. Non-protein nitrogen was determined in a Folin-Wu

filtrate of whole blood, as was the amino-nitrogen. The former determination was done by the method of Folin and Wu (1919), and the latter by van Slyke's method (1929). Blood cholesterol levels were determined by Leiboff's method (1924), the blood proteins by Andersch and Gibson's (1933) modification of Wu and Ling's method. Urinary nitrogen was determined by the Kjeldahl method, and the creatinine and "total creatinine" by the colorimetric method of Folin (1914). The total sulphates (inorganic plus ethereal sulphates) were estimated by the method of Folin (1905). Some difficulty was experienced in obtaining consistent results in total sulphur estimations until a method after Pirie (1932) was used. Estimations on each individual sample were repeated until a constant value was obtained. To check these results a pooled sample made from proportional parts of each daily sample was prepared and the sulphur content estimated. The final value obtained from the pooled sample was within 2% of the sum of the values from the individual samples.

#### Comment on Laboratory Investigations

The first abnormality revealed by the routine investigations was the rise in the serum bilirubin level between 12.30 p.m. and 6.30 p.m. on Oct 3—i.e., during the period when the liver was enlarging rapidly. Apart from the rise in blood amino-nitrogen at the end of the period of infusion and the transient appearance of urobilinogen on the day when relapse occurred, the routine investigations showed no other significant abnormality. It is of interest to note that the serum bilirubin on Nov. 2 had remained at the same level as on the day before discharge (Oct. 13).

In addition to these routine tests an attempt was made to follow the mode of action of methionine by estimating the nitrogen and sulphur balances of the patient and by determining the partition of the urinary sulphur between the oxidized (total sulphate) and unoxidized (neutral) fractions. It would appear from the balance figures that there was a nitrogen retention of 6 g. over the whole period. This may well be accounted for by nitrogen loss in the faeces. It should be noted, however, that on the 3rd and 4th there was a total negative balance of 7 g., which was almost eliminated by the sum of the positive balances of the 5th and 6th. While it is difficult to believe that the negative balance represents the rapid destruction of cellular elements followed by an equally rapid replacement, it may well be that on the 3rd and 4th the processes of protein synthesis in the liver were impaired, but returned to normal on the 5th and 6th and continued so during the rest of the period of observation.

The positive sulphur balance is, however, proportionately much greater. Even when a 5% error in estimated intake, a faecal loss of 10%, and an error of 2% in the total urinary sulphur estimations are deducted from the positive balance, there is still a small amount of sulphur unaccounted for. Since it is unlikely that all these factors operate at a maximum value and in the same direction the retention of sulphur is probably significant.

That the liver damage was in the nature of a metabolic derangement rather than an actual destruction of liver substance is indicated by the partition of the urinary sulphur. We have not yet followed the metabolism of large quantities of methionine given intravenously to normal individuals. Medes (1937), however, has shown that of 3.2 g. of *dl*-methionine given orally to normal individuals 95% is oxidized to sulphate and excreted in the urine within 24 hours, causing no appreciable rise in the unoxidized sulphur fraction. As it has also been shown by Martin and Thompson (1943) that amino-acids injected at the rate of 10 g. an hour do not spill over into the urine, it is safe to assume that a normal individual receiving the same treatment as our patient would have excreted in the urine the major portion of the methionine sulphur as oxidized (total sulphate) sulphur within 24 hours. The rate of injection of the solution used in our patient was almost identical with that quoted by Martin and Thompson. Our patient, however, excreted an excessive amount of unoxidized sulphur during the first two days, a quantity which was roughly equivalent to 65% of the amount of sulphur given therapeutically as methionine. While there is a possibility that some of the unoxidized sulphur excreted on the first day might be

due to spill-over into the urine, this cannot be true of that excreted on the second day. Moreover, a similar phenomenon was noted on the day of relapse, when the methionine was given orally. Thereafter the neutral sulphur fraction was within the usually accepted normal limits.

These considerations lead us to believe that the intimate cause of the liver disturbance induced by carbon tetrachloride is an abnormal metabolism of methionine and related compounds, and, moreover, that in our patient it was specifically the administration of methionine which prevented further liver damage. We hope to be able to determine the degree of permanent liver damage, if any, and the patient's response to large doses of methionine when he is readmitted to hospital for investigation at the end of six months.

#### Summary

The history of a case of acute carbon tetrachloride poisoning has been presented.

The patient was treated successfully by *dl*-methionine administered partly by infusion and partly by mouth.

An attempt has been made to follow the metabolism of the methionine administered.

We wish to express our thanks to Col. Middleton and Col. Hatcher, U.S. Army Medical Corps, for putting hospital and laboratory facilities in a U.S. Military Hospital at our disposal. We are grateful to Dr. M. Smith and Miss W. Watts for their assistance with the laboratory investigations, to Miss Eisendorff for superintending the dietetic work, and to the ward and laboratory staffs for their co-operation. We wish to thank the Research Department of British Colloids Ltd. for providing generous samples of casein digests suitable for intravenous injection.

## A CLINICAL EVALUATION OF SOME TESTS OF LIVER FUNCTION

BY

G. HIGGINS AND J. R. P. O'BRIEN  
Department of Biochemistry, University of Oxford

ALICE STEWART AND L. J. WITTS  
Nuffield Department of Clinical Medicine

(Radcliffe Infirmary, Oxford)

Before biochemical tests are accepted for the diagnosis or assessment of disease of the liver in man they should conform to certain conditions. First, it is essential to know the extent of the normal variations. To do this the tests must be applied to a large number of healthy men and women of different ages. Secondly, the tests should be applied in proved disease of the liver to show their sensitivity. To be satisfactory the results should differ materially from those found in the normal series. Detailed analysis might also reveal points by which one could distinguish between the various forms of liver disease and judge the severity of the liver damage. Thirdly, the tests should be applied in other diseases to show how specific they are.

Only when tests have been considered from these stand-points can they justifiably be applied to unselected clinical material. Although obvious, these criteria have often been ignored in the past, and even now are not fully appreciated. The number of observations on control cases is often small, and the worth of the tests in the diagnosis of disease of the liver is often open to doubt. Applied to cases in which the diagnosis is uncertain, they have given abnormal findings which have led to the assumption that the patient is suffering from disease of the liver. Then, by a familiar logical fallacy, it

is argued that the tests are good tests because they have revealed disease of the liver. In the work here presented a determined effort has been made to break this vicious circle and to put the first two conditions of validation on a sound statistical basis. Final proof of the exact specificity of the tests would include repeating them in every known disease. This is clearly impossible, but the tests have been done in a large group of miscellaneous diseases.

The biochemical investigations reported here are part of a much larger study of pigment metabolism (O'Brien, 1944), and only those immediately concerned with liver function are given. These are attempts to assess the efficiency of the liver in performing certain biochemical activities ascribed to it, and include tests to demonstrate the part it plays in carbohydrate metabolism and protein synthesis, and its ability to secrete, excrete, and detoxify certain organic compounds. The following estimations were made:

*Plasma Bilirubin*: Colorimetric (Thannhauser and Andersen, 1921)

*Plasma Phosphatase*: Colorimetric (King and Armstrong, 1934)

*Plasma Proteins*: Micro-Kjeldahl (Howe, 1921)

*Hippuric Acid Test*: Titration (Probstein and Londe, 1940)

*Modified Laevulose-tolerance Test*: Colorimetric (Higgins, O'Brien, and Stewart, 1942). The laevulose index is derived from this test.

100 individuals—50 males and 50 females between the ages of 18 and 50 years, all university students or laboratory personnel—were used as controls.

#### Diseases of the Liver

The patients studied comprised all suitable cases of disease of the liver admitted to the Radcliffe Infirmary during the past three years. Many of the patients were kept under continuous observation, and the tests were repeated during the course of the illness. The others were made the subject of a special follow-up investigation in the summer of 1943. Several of the patients who had recovered were re-examined some months after their discharge from hospital. Biochemical data were completely disregarded in making the diagnosis, which was founded on clinical criteria. The following diseases are represented:

*Secondary Carcinoma of the Liver (16 Cases)*.—The diagnosis was confirmed either at operation or at necropsy. For the purpose of statistical analysis two groups are recognized—one with intense jaundice due to extrahepatic obstruction (9 cases), and one in which there was no compression of the large bile ducts (7 cases).

*Acute Hepatitis (22 Cases)*.—These were all cases of acute parenchymatous disease of the liver in which the illness was of short duration. Fifteen were probably cases of infective hepatitis, and one developed jaundice after an operation for appendicitis and intensive sulphonamide therapy. There were five cases of post-arsphenamine jaundice, two cases of Weil's disease, one of which was fatal, and one fatal case of acute hepatitis of unknown aetiology. Post-mortem examination in the two fatal cases showed acute diffuse hepatitis with no residual scarring.

*Subacute Hepatitis (19 Cases)*.—These were cases of hepatitis with jaundice in which the illness lasted longer than two months. In every instance jaundice was the presenting sign, and investigation excluded the presence of gall-stones or neoplasm. Eight patients died, six showed complete clinical recovery at the time of the follow-up, and five were still suffering from recognizable liver disease. Post-mortem examination was made in all the fatal cases, and revealed massive necrosis with scarring and nodular hyperplasia.

Of the six patients who recovered two were cases of post-arsphenamine jaundice, one had been exposed to T.N.T., and three were probably cases of infective hepatitis.

Three of the eight patients who died had had previous attacks of jaundice, diagnosed at the time as infective hepatitis. One had worked in a laundry and handled trichlorethylene for a number of years. There was no clue to the aetiology in four of the cases.

The five patients who showed progressive disease of the liver but were alive at the time of the follow-up included one who had used carbon tetrachloride as a cleaning agent for many years. He had a

mild attack of jaundice while on holiday. He returned to work immediately afterwards, but continued to feel ill, and two months later the jaundice recurred. One patient dated his illness from an attack of jaundice that occurred during an epidemic of infective hepatitis, and he gave a definite history of contact at this time. There was no clue to the aetiology in three of the cases.

*Cirrhosis or Chronic Hepatitis (14 Cases)*.—The onset of the illness in this group was insidious and not marked by any recognizable clinical event. The disease either was discovered accidentally in the course of investigating other conditions or was first seen when symptoms of portal hypertension or terminal liver failure had developed. In every case the liver was inspected either by laparoscopy or laparotomy or at necropsy. One patient gave a history of syphilis and one had haemochromatosis. Both these patients died, and the diagnosis was confirmed post mortem. Three were chronic alcoholics, one of whom also took drugs. One had been treated for epilepsy with Fowler's solution for several years. Six of the fourteen patients died. The tests were repeated in six of the eight who were alive at the time of the follow-up. The essential pathological lesion in the fatal cases was diffuse periportal fibrosis with minimal parenchymatous hyperplasia.

The cases of subacute hepatitis that failed to recover often presented in the later stages of their illness a clinical picture which was indistinguishable from that of cirrhosis. We have used the presence or absence of jaundice early in the disease as the clinical distinction, but it is possible that there is no hard-and-fast line between these two groups. On the other hand, the subacute cases that recovered resembled the case of acute hepatitis in every respect except that the jaundice was more prolonged. The impression gained from the survey as a whole is that in diffuse hepatitis, as in glomerulo-tubular nephritis, every grade of chronicity exists, but for purposes of classification and statistical analysis the subdivision into acute subacute, and chronic hepatitis is convenient, and enables one to relate the biochemical abnormalities to the clinical course and prognosis.

#### Diseases of Other Systems

Investigations were made in 62 cases of illness other than disease of the liver. The following disease groups were represented:

	Cases		Cases
Anaemia .. .. .	18	Ulcerative colitis .. .. .	2
Secondary syphilis .. .. .	18	Type II nephritis .. .. .	2
Reitveldt's .. .. .	6	Hypertension .. .. .	2
Thyroiditis .. .. .	5	Myelomatosis .. .. .	1
Thyroiditis .. .. .	5	Polycythaemia .. .. .	1
Diabetes .. .. .	4	Arsenical dermatitis .. .. .	1
Peptic ulcer .. .. .	3	Lung abscess .. .. .	1
Ascites from other causes .. .. .	3		
Carcinoma .. .. .	3		

#### Results

The results from all three groups are summarized in Table I which gives the mean value and the standard error of the mean for each test. Table II gives a more detailed analysis of the tests in the liver diseases.

##### 1. Normal Controls

The complete battery of tests was done on every individual. This is one of the largest control groups for this series of tests yet reported, and should give reliable information regarding the range of values in the healthy adult population living under the wartime conditions of 1942. The results are being reported in detail elsewhere (Higgins and O'Brien, 1944).

##### 2. Disease of the Liver

*Plasma Bilirubin*.—Both the fatal cases of acute hepatitis were intensely jaundiced. This was also a feature in the early weeks of the illness in the more severe cases of acute and subacute hepatitis that eventually recovered. The last group contained two gravely ill patients in whom the bilirubin was over 20 mg. per 100 c.cm. when first seen. These bilirubin values cannot properly be compared with the ones found in the cases of subacute hepatitis that failed to recover, because these patients were often not sent to hospital until several months after the jaundice had first appeared. None of the cases of cirrhosis gave a history of a previous attack of jaundice, and even in the terminal stages of this disease a rise in the plasma bilirubin of more than 2 or 3 mg. was exceptional. As might be expected, there was intense bilirubinaemia

the cases of carcinoma with extrahepatic obstruction, and by moderate jaundice in those in which there was none.

**Plasma Phosphatase.**—The average value for the plasma phosphatase was above normal in each group. The two fatal cases of acute hepatitis gave values of 18 and 22 units respectively. In the cases of hepatitis that recovered the level of plasma phosphatase ranged from 10 to 54 units at the height of the illness, with a mean value of 24 units. In every case except one the level returned to normal when the patient recovered. The exception was a boy with subacute hepatitis. His plasma phosphatase was still 35 units six months after the beginning of the illness. Variable results were obtained

the thirteen cases in this group had more than 2.8 g. % albumin when first seen, and six of the eight fatal cases gave terminal values of less than 2 g. %. Three of the five cases that were still alive had just over 3 g. % albumin when last seen.

Low values were also found in the patients with cirrhosis, but three of the fourteen cases had more than 3.5 g. % albumin when first seen. These three patients were alive and well at the time of the follow-up. Only one patient had less than 2 g. % albumin, and he died within a month. In both types of carcinoma of the liver the plasma albumin was subnormal, and ranged from 3 to 4 g. %.

The fall in the plasma albumin was accompanied by a rise in the plasma globulin in many cases of hepatitis. In one of the fatal cases of acute hepatitis and in thirteen of the acute and subacute

TABLE I.—Liver Function Tests in 100 Controls, 71 Cases of Liver Disease, and 62 Cases of Other Diseases

	No. of Cases	Bilirubin (mg./100 c.cm.)	Phosphatase (units)	Plasma Proteins (g. %)			Hippuric Acid (% excretion)		Laevulose Index
				Total	Albumin	Globulin	2 Hours	4 Hours	
Controls	100	0.5 ± 0.33	8 ± 2.0	7.1 ± 0.38	4.6 ± 0.29	2.2 ± 0.35	59 ± 9.2	88 ± 6.1	11 ± 1.15
Liver diseases	71	8.4 ± 3.46	33 ± 2.52	6.8 ± 0.12	3.2 ± 0.09	3.2 ± 0.13	35 ± 1.7	62 ± 1.7	27 ± 1.60
Other diseases	62	0.64 ± 0.05	12.4 ± 1.44	6.7 ± 0.11	4.0 ± 0.08	2.3 ± 0.09	55 ± 1.8	80 ± 1.4	13.8 ± 0.35

In this and the following table the mean values and the standard error of the means are shown for each test. The laevulose index is the sum of the maximum value blood laevulose plus the value at 24 hours after ingestion of 100 g. sucrose.

(a) When first seen. (b) After recovery. (c) 3 to 8 months later. (d) Within 1 month of death. (e) 9 months to 2 years later.

the cases of subacute hepatitis that failed to recover. The average value was 26 units, but there was a wide scatter and close correlation between the level of the plasma phosphatase and the clinical condition. In six of the thirteen cases it was low 20 units when first seen, and low values were found in the terminal stages of three of the fatal cases. Four cases of cirrhosis gave values of less than 20 units when first seen, but the average value, 36 units, was much higher than in the other types of hepatitis. When the tests were repeated at the time of the follow-up only one case of cirrhosis gave a value of less than 40 units. In the cases of carcinoma of the liver with extrahepatic obstruction the plasma phosphatase was usually higher than in any other group, ranged from 20 to 96 units, with an average value of 62 units. In the cases of carcinoma without extrahepatic obstruction the average value was 37 units, with a range from 10 to 80 units.

**Plasma Proteins.**—Changes in the plasma proteins occurred in each group, and in the cases of hepatitis in which the illness lasted more than two months a close correlation was observed between the fall in the albumin and the extent of liver damage. Where the latter was greatest, as in the fatal cases of subacute hepatitis, there was also a remarkable rise in the plasma globulin.

The two fatal cases of acute hepatitis had 3.5 and 3.3 g. % albumin. Twenty of the twenty-four cases of acute and subacute hepatitis that recovered had less than 4 g. %. Only four had less than 3 g. %.

The plasma albumin was lowest in the cases of subacute hepatitis that failed to recover. It became still lower as the clinical condition deteriorated, but improved during a remission. Only one of

cases that recovered the globulin was over 3 g. %. In spite of this, in eleven cases of acute hepatitis and in four cases of subacute hepatitis that recovered the total protein was less than 7 g. %.

In the cases of subacute hepatitis with progressive disease of the liver there was usually a remarkable rise in the plasma globulin, which became still greater as the disease advanced. Only one of the fatal cases had less than 3.7 g. % globulin in the terminal stage of the illness. The increase in the globulin was often responsible for a rise in the total protein, and in seven cases this was over 8 g. %. The highest globulin values recorded were 7.2 and 7.7 g. %, the corresponding total protein being 9.2 and 9.8 g. %.

The rise in the plasma globulin was less striking in cirrhosis than in the fatal cases of subacute hepatitis, but ten patients had over 3.2 g. %. The total protein was less than 6.8 g. % in ten cases and over 8.8 g. % in two cases. The six patients re-examined during the follow-up showed a greater change in the albumin-globulin ratio than was observed when they were first seen.

The globulin was usually not increased in carcinoma. In only one instance was it over 3 g. %, and in other cases it ranged between 1.7 and 2.4 g. %. The total protein was less than 6.7 g. % in every case except one.

**Hippuric Acid Excretion.**—In each group the average value for the amount of hippuric acid excretion was subnormal, but there was a wide variation in the individual figures and no close correlation between the amount excreted and the severity or duration of the illness. There was no reliable distinction between the different disease groups. The average two-hourly excretion was slightly lower in the cases of cirrhosis and subacute hepatitis with progressive disease of the liver than in the cases of hepatitis that recovered, and lower in the cases of carcinoma with extrahepatic obstruction than in those without, but there was no difference in the average value for the amount excreted in four hours. Hippuric acid excretion

faced in an upper compartment with connecting flues. Ingley (1943) has lately constructed and used a similar refrigerator.

If the rationale of this treatment be accepted, frost-bite casualties on arrival at a C.C.S. or base medical unit should have the affected limbs inserted in a cooling cabinet, where they would remain until the circulation had been re-established and the greater part of the oedema had disappeared. During this period the temperature of the cabinet could be gradually increased daily until it reached room temperature. The length of time required for this "controlled thawing" would be several days, depending on the severity of the lesion.

### Extremity Wounds, with Impaired Blood Supply

In an extremity in which the wound or injury has impaired the blood supply sufficiently to produce a danger of ischaemic gangrene one has a fundamentally similar problem. The ischaemia which is responsible for the oxygen deficit in the tissues may be due to ligation of main arteries, destruction of collateral branches, or intense swelling and oedema exerting pressure in fascial compartments and hindering the normal transfer of oxygen to the tissues.

To refrigerate the distal extremity of limbs with dangerously impaired blood supply, from whatever cause, appears perfectly reasonable. By so doing one lowers the metabolic requirements of the endangered tissues until such time as the collateral circulation has been established and swelling has subsided. It has been proved experimentally (Brooks and Duncan, 1940; Allen, 1941) that the ischaemic limb or tail of an animal survives a great deal longer when treated by dry cold than when left at room temperature. Allen also observes that the cold apparently inhibits blood-clotting and thrombosis, and he has demonstrated clinically that it prevents the coagulation of exudate in wound margins, thus facilitating drainage while retarding healing. Further benefits from cold therapy would be the relief from pain and the inhibition of any infective process that may be present in the affected part until such time as an improved blood supply might deal with it more effectively.

It may be argued that cold applied to the limb will induce a degree of arterial spasm and thus hinder the development of a collateral circulation. Very low temperatures, however, need not be used, and any tendency to vasospasm could be offset by coincident anaesthesia of the sympathetic nerve supply, heat applied to the other limbs, or vasodilator drugs. It is also possible that some phase of the biochemical process of tissue oxidation may be inhibited by too low a temperature, and in such an instance cold therapy could conceivably be helpful. If this is the case some form of temperature regulation is necessary.

The above experimental and clinical observations, based on apparently sound theory, should warrant investigation into the treatment of limb extremities, in certain types of wounds, by dry cooling and a gradual return to room temperature.

### Traumatic Arterial Spasm

Increasing attention has been paid by surgeons recently to the occurrence of an arterial spasm associated with some wounds and fractures of the extremities (Cohen, 1940; Griffiths, 1940; Barnes and Fructa, 1942; MacFarlane, 1942). In such cases there is a history of trauma to the artery, which on exposure may or may not reveal any obvious evidence of damage. The resultant spasm has been shown experimentally (Barnes and Fructa, 1942) and clinically by these investigators to involve in most cases the entire vascular tree of the limb, and leads sometimes to gangrene. Griffiths has recently concluded that Volkmann's ischaemic contracture "is due to arterial injury and to the accompanying spasm of the arterial circulation." The pathology of the muscle necrosis in this condition and so-called traumatic arterial spasm has been observed to be similar (MacFarlane, 1942).

Cold therapy has already been considered and used by Canadian Army surgeons for traumatic arterial spasm. Again it must be remembered that cold in itself produces certain degrees of arterial spasm, and only further investigation will prove that in the balance greater benefit is conferred by its ability to lower the metabolic requirements of the tissues.

Acting on this latter assumption, however, these limbs can be refrigerated as an adjunct to the specific forms of therapy already recommended, such as surgical exposure of the artery, sympathectomy, arteriectomy, and the use of vasodilators. Since it has been observed that this spasm sometimes disappears spontaneously after a few days with the return of arterial pulse, cold therapy could be used as part of the conservative therapy routine provided no undue compression of the artery is considered likely to exist.

### Peripheral Embolism

Acting on the same principle, and already suggested by Allen, dry cooling of a limb in which there has been an embolic blockage of its blood supply would enable the tissues to carry on at a reduced metabolic rate until the establishment of an improved circulation. Whether in conjunction with embolectomy or other lines of conservative treatment, tissue vitality would theoretically be retained during the time required for relief of the associated vasospasm or the development of a collateral circulation.

### Description of Unit

The unit (Figs. 1-3) has been designed to accommodate two limbs if necessary. The cabinet or limb unit is cooled by cold brine, which circulates through coils in the wall, the

FIG. 1.—Side view of limb cabinet. *a*, Front panel with frame and slings attached. *b*, Studs for securing front panel. *c*, Trough with drain for condensate. *d*, Castors on front of frame. *e*, Guide for castors. *f*, Cork insulation. *g*, Brine pipes soldered to inner walls. *h*, Brine return pipe. *i*, Thermometer bulb. *j*, Thermometer dial. *k*, Canvas sleeve. *l*, Holes in front panel for entry of limbs. *m*, Brine-flow regulating valve. *n*, Hose union for brine pipe from reservoir.

FIG. 2.—Perspective of limb cabinet, showing one canvas sling. (For explanation of lettering see Fig. 1.)

temperature of the cabinet being regulated by merely adjusting the rate of flow of cold brine, using a stopcock and thermometer, conveniently placed for the patient to do his own adjusting.\* The slings for the limbs are suspended from

\* This method was used satisfactorily on the experimental model, but it has since been determined that it would be possible to have an automatic valve made which would pass just the requisite amount of brine to maintain the cabinet at any predetermined temperature. The whole equipment would thus be independent of any manual control.

a metal framework which is integral with the front panel. Thus by detaching the front panel the limbs can be withdrawn for observation or dressings with a minimum of trauma and without disturbing their position in the slings. This operation is facilitated by the provision of castors on the far end of the frame running in guides on the floor of the cabinet.

The brine circulating in the limb cabinet is cooled in a reservoir to a predetermined temperature by a separate refrigerating machine and pumped to the limb cabinet through a flexible tube. Several limb cabinets can be attached to the brine supply at one time, thus allowing treatment of more than one patient, and by adjusting the stopcocks (previously described) on the limb cabinets it is possible, if necessary, to maintain different temperatures in each of the cabinets.

The actual refrigerating machine with brine reservoir would be a mobile unit mounted on a trolley and operated entirely by electricity. Its essential components would be a small compressor operated by an electric motor, an air-cooled condenser, and an automatic expansion valve for regulating the flow of refrigerant. The brine reservoir

vaporized would be pumped out by the compressor and recondensed in the air-cooled condenser. The brine could be kept within  $2^{\circ}\text{C}$  of any desired temperature by means of a thermostat, which would automatically start and stop the electric motor driving the compressor. The cooled brine would be taken from the reservoir by a small electrically driven centrifugal pump, and circulated to the various units by way of a manifold and flexible hoses, returning afterwards to the reservoir for re-cooling. It is estimated that the dimensions of a complete refrigerating unit as described, and capable of operating up to four limb cabinets, would not exceed 2 ft. 6 in. by 2 ft. 6 in. by 2 ft. 3 in.

The cabinet described can be operated over a very wide range of temperature. It has been determined experimentally that in order to maintain a cabinet temperature of  $4^{\circ}\text{C}$ . to  $6^{\circ}\text{C}$ . the brine circulating need only be  $0^{\circ}\text{C}$ . to  $-2^{\circ}\text{C}$ . Therefore, by lowering the temperature of the brine reservoir, which is done by adjustment of a thermostat, temperatures well below freezing-point could be maintained in the cabinet.

The working model constructed by one of us (Lanyon) for investigation has a small limb cabinet capable of accommodating a hand and lower forearm (see photographs, Fig. 3). Observations made on an empty cabinet and again with a normal limb inserted proved the ability of the cabinet to assume any given temperature and to maintain this temperature with the minimum of adjustment. Dermatherm readings, to record the resultant changes in skin temperatures, made by attaching a thermocouple to the dorsum of the hand, showed coincident variation of skin temperatures (see Graph). With such an apparatus, cabinet temperatures from  $4^{\circ}\text{C}$ . to room temperature were obtained. After two hours' exposure at a cabinet temperature around  $12^{\circ}\text{C}$ . the limb appears to be completely chilled, evidence of this being the subjective numbness and the fact that it takes several hours for the skin temperature to return to normal after removal from the cabinet.

### Summary

A description is given of a refrigerating device to investigate the dry cold treatment of frost-bite, traumatic arterial spasm, peripheral embolism, and certain wounds of the extremities.

Observations made on a working model have proved it capable of providing the conditions necessary for such treatment.

The apparatus is simple, portable, and flexible in operation, and has been designed primarily to meet the requirements of an army in the field.

We acknowledge with thanks the helpful advice of Lieut.-Col. E. H. Botterell, Basingstoke Neurological and Plastic Surgery Hospital, and the facilities provided by the Officer Commanding Army Blood Supply Depot for carrying out the experimental work.

A new decree has been issued in Rumania which states that everyone with venereal disease must undergo treatment, and premarital certification of freedom from infection is obligatory. Physicians must report defaulting patients. Persons exposed to risk through their profession—e.g., those serving in hotels, restaurants, night clubs, public baths, as well as pedlars and street vendors—are subject to periodic examinations. Correctional imprisonment of 1 to 3 years is imposed on clandestine prostitutes and proprietors of hotels who allow prostitution on their premises. Knowing transmission of the disease to others carries a sentence of 1 to 5 years' correctional imprisonment and a fine of 50,000 to 200,000 lei. . . . Persons undergoing medical treatment at the time of transmission of the disease will be severely punished without the application of extenuating circumstances. Free blood tests are made by the State. Brothels are again permitted by law.

would be mounted alongside the machine, and would consist of an insulated tank with a suitable coil of cooling pipe immersed in the brine. This coil would be cooled by admission of liquid refrigerant through the expansion valve; the refrigerant when

## AETIOLOGY OF "IMMERSION FOOT"

BY

B. W. GOLDSTONE, M.B., B.Sc., F.R.C.S.Ed.

Major, R.A.M.C.

AND

H. V. CORBETT, M.D., M.Sc., M.M.S.A., D.R.C.O.G.

Major, R.A.M.C.

Shipwrecked men adrift on rafts, at times half covered with sea-water, are subject to the lesions of "immersion foot" and "immersion hand." The war has obviously caused a great increase in the number of these cases, yet the clinical descriptions available were scanty until Ungley and Blackwood (1942) published their careful observations. We have now seen four parties of men rescued after many days at sea in a half-soaked state. These cases showed features that surprised us; especially the fact that the lesions had occurred at a time when the temperature never reached freezing-point, and in one instance during the summer. This was contrary to all our preconceived ideas of the lesion, which was previously assumed to be similar to a slow frost-bite. Our purpose in this paper is (i) to confirm the clinical picture as established by Ungley and Blackwood (1942); (ii) to present a conception of its aetiology; (iii) to describe a remarkable complication.

There were four parties of rescued men. The numbers were respectively 9, 1, 1, and 10. Nearly all showed roughly the following syndrome, some having interesting complications which will be described afterwards.

## Swollen Stage

This stage was present soon after they were taken from the water. The hands and feet were greatly swollen and the skin was shiny. The extremities showed muscular paresis and there was complete anaesthesia both of hands and of feet; in some cases the anaesthesia extended as high as the middle of the lower leg. Pain was not a marked feature at this stage. There was pyrexia for a few days.

## Stage of Diminishing Oedema

After about a week the hands and feet shrank. The skin was no longer shiny, but wrinkled and dull; anaesthesia was passing off, though it was still present at the extreme distal parts—e.g., soles of feet. Paraesthesiae were present; these ranged from mere pins-and-needles to agonizing pains which prevented sleep for many nights. These pains often continued for several weeks with diminishing severity. Frequently there was so much tenderness that the patient could not bear the weight of the sheets upon his toes. Even when the lower leg bore no outward mark of any lesion, there was often agonizing pain on pressure at the lower part of the calf and tendo Achillis, and the ankle-jerks were diminished or absent.

It will be seen that the whole clinical picture bears a pronounced resemblance to a condition of peripheral neuritis. The muscular paresis, the anaesthesia, the agonizing pains, and the frequent absence of reflexes all help to build up this resemblance. Throughout this stage the feet are warm and the pulsation of the dorsalis and posterior tibial arteries is good.

## Complications

**Gangrene.** In the first party of 9 cases gangrene did not occur. It was seen in the third party. In this one case the man had drifted for 15 days, in summer weather, with his feet partially immersed, and gangrene of the fore part of the feet and of the heels occurred. We saw this case only at a very late stage, by the kindness of Mr. McIndoe. There had certainly been gangrene; according to the patient's own statement, tingling followed by numbness began on the third or fourth day, and thereafter he noticed the gradual onset of blackness of the feet. There was no pain, but he was aware of what was happening. Gangrene probably became certain about the seventh or eighth day. The fourth party—10 men—had been waterlogged for 50 hours in very mild weather. Of these, one man had only slight superficial gangrene of the skin of the knuckles on one hand. This hand had been continually grasping a rope of the raft without letting go. It was quite obvious that the gangrenous patches corresponded to the whitening of the knuckles (and consequent ischaemia) that would result from the continual clutching. We feel that gangrene is not an essential or even a common feature of the typical lesion, and would appear to occur under exceptional conditions which would kill any normal man long before the onset of foot gangrene.

**Skin-water Rash.** This occurred in two of the cases. It consisted of minute boils spread over the skin. It appeared only on the chest, and we have not yet seen it in relation to the typical lesion of immersion foot. Its interest lies in the manner in which the toxic

action of the salt water on the skin is shown in its fullest form—as apart from the action of cold.

**Duodenitis.**—We do not know how common this complication is, but as it certainly occurred in one, and possibly two, of our series, we shall describe it. The first patient, about a week after his rescue, began to pass altered blood and then bright blood per rectum. He rapidly became exsanguinated. A diagnosis of possible bleeding duodenal ulcer was made, although no previous history of ulcer could be obtained. His condition gradually became worse, and in spite of transfusions he died. The following is an extract of the necropsy report:

"The stomach contained a little mucoid fluid and had pale walls. The whole of the small intestine and much of the colon were filled with a dark tarry faecal material. There was no tumour or ulcer visible in the wall, but the whole of the duodenum was deeply engorged and oedematous—obviously the origin of the fatal haemorrhage. The liver weighed 70 oz. and had a smooth grey surface. The substance was soft, and showed bile staining around many of the intrahepatic channels. The kidneys weighed 11 oz. Their capsules stripped from a smooth pale surface. On section, differentiation of structure was poor and there was some cloudy swelling. . . . In my opinion the cause of death was: (a) small-intestinal haemorrhage; (b) acute toxic hepatitis and nephritis; (c) chilling of both legs from prolonged immersion."

The second patient, apart from any leading questions, complained of fairly severe epigastric pain 1½ to 2 hours after meals. He had never before had dyspepsia, and the type of his pain is suggestive of duodenitis.

## Discussion

Greene (1941) stated: "I gather that clinically it [immersion foot] is almost identical with trench foot." He also stated that "trench foot is almost identical with gradual frost-bite." We wish to draw a clear distinction between the two conditions (frost-bite and immersion foot) for the following reasons:

Lewis and Love (1926) have shown that very probably the essential feature in production of frost-bite is actual freezing of the skin. They demonstrated that if the freezing-point of the skin could be depressed (as by inunction with oil) it would be relatively protected from frost-bite. They showed, in fact, that it would need to fall to  $-2.2^{\circ}$  C. at least for the skin to freeze. In the evolution of our cases the temperature never fell below zero, according to the cases at our disposal. We stress this point because a clear-cut phenomenon like freezing most probably changes the living cell immediately; its metabolism would cease, and its membrane must run the risk of bursting by reason of the sudden formation of ice within it. As Lewis and Love (1926) state, "The hardening and firm union of [ice] crystals, at first separate, is an event especially calculated to produce cellular damage, and it is to cellular damage that the after-effects must be ascribed, for they are in all respects similar to those produced by mechanical injuries delivered from outside—for example, the lash of a whip."

The aetiology of immersion foot is a gradual chilling, never frost. This chilling produces a vicious circle when the familiar protective reflex of local arteriolar spasm is superadded. Thus all tissues soon begin to suffer from a combined insult—cold and relative ischaemia. The weakest tissue would suffer most. It is logical to suppose that the biologically most delicate tissue would show the lesion first. Nerve tissue is probably the most delicate, hence the syndrome of peripheral neuritis is the predominant clinical feature. Support for this view is especially furnished by two of the cases. In both of these the tissue of the lower leg revealed no sign of skin damage, yet both showed signs of peripheral neuritis; one had anaesthesia of the lower calf, and the other great tenderness on deep pressure of the calf and an absent ankle-jerk. Since originally writing this we have read Ungley and Blackwood's (1942) paper. Their microscopical observations on post-mortem material confirm this point—namely, that Wallerian degeneration was the outstanding lesion.

It is obvious that if the chilling process is sufficiently prolonged the metabolic handicap would become intolerable to each tissue in turn. Thus each tissue, in the order of its strength, would successively fail in its function, then die. Finally, the lowest and most tolerant of all tissue (connective tissue and tendon) would fail to survive the more organized tissues. The whole part would then be gangrenous, as in the case of one of our patients who was 15 days on a waterlogged dinghy. Probably few men could survive this long test, and gangrene is therefore a rare occurrence in the disease of

immersion foot. Is cold, then, directly the major factor in the metabolic handicap, or is the relative ischaemia—an indirect result of the cold—principally responsible for the lesion? Both views are considered by Ungley and Blackwood (1942), who fully discuss the two theories. It seems more probable that ischaemia is the responsible agent.

The aetiology of frost-bite is quite different. In its purest and most dramatic form it occurs suddenly, as in the case of Greene's (1940) experience with a camera shutter. He states: "The contact of a momentarily ungloved finger with the button of a camera in a high wind at a temperature below zero Fahrenheit and at a height of about 25,000 ft. once cost me a finger-tip." Here we have a sudden mechanical accident. It produces the familiar appearance (like a localized infarct) of frost-bite. Within this area all tissues, irrespective of their biological resistance, are dead. In the mechanical explosion the strong have perished with the weak.

Of course there must be mentioned forms in which frost-bite becomes superadded to immersion foot. We have never seen trench foot, but in this there would be an opportunity for a combination of the two syndromes: a succession of rain, mud, and slush would give the prolonged chilling sufficient for the development of immersion foot; and, as Lewis and Love (1926) have shown, by the washing away of skin oils would, with the advent of frost, predispose the tissues to the development of frost-bite if the temperature suddenly fell below freezing-point.

### Other Complications

**Salt-water Boils.**—It might be objected that the syndrome we describe could have been caused by either the chemical or the osmotic action of the sea-water and not by the chilling effect. However, the location of salt-water boils on the chest in two of our cases should answer this objection. The chest, by reason of its rich blood supply and high mass-surface ratio, is not liable to cooling, and would therefore show a pure result of toxic action as apart from chilling. With regard to osmotic action, sea-water is about 21 times as strong osmotically as human tissues. No osmotic action could have occurred through the skin, otherwise the tissues would have shrunk and not swollen.

**Duodenitis.**—Nearly all our patients had pyrexia in the early stages; they were not infected. This must have been non-specific traumatic fever, caused by the absorption of toxins from traumatized areas. Curling's ulcer of the duodenum occurs as a result of absorption of toxins from burnt areas. The similar aetiology of Curling's ulcer and our case of duodenitis is certainly striking, but it would be beyond the scope of this paper to speculate on the mechanism of this duodenitis.

### Treatment

From time immemorial the danger of rapidly warming frost-bitten areas has been recognized. Greene (1942) has given a scientific basis to this idea by freezing a rat's tail and then thawing it in front of a fire. This caused the loss of nearly twice the tissue that would otherwise have occurred. Smith, Ritchie, and Dawson (quoted by Greene, 1940) suggest that it may be due to rupture of capillaries previously damaged by frost. Lewis and Love (1926) suggest that the presence of histamine-like substances causes an excessive and dangerous transudation.

It might be thought that these considerations were not specially applicable to cases of immersion foot. But Ungley and Blackwood (1942) sound a word of warning against the use of heat. They quote the experiment of Allen on chilled ischaemic rats' tails. These survived much longer than the unchilled controls. He suggests, therefore, that in a recent case of immersion foot it is dangerous to warm the part before circulation has returned: warmth raises its metabolism to a point beyond the capacity of the feeble circulation to supply it. Thus the tissues are rapidly brought to a state of metabolic bankruptcy, and necrosis occurs.

It should be noted that the theoretical objections to warmth in the treatment of frost-bite are based on the vasodilator effect of heat.

We refer again to Lewis and Love's experiment in which vesicle formation on warming a frost-bitten part was minimized

by compressing the main limb artery. Smith, Ritchie, and Dawson (quoted by Ungley and Blackwood, 1942) stated that actual rupture of frost-bitten capillaries occurred with too forceful vasodilatation. The objection to heat in cases of immersion foot, however, is somewhat different. The rise of temperature is considered undesirable because it raises the metabolic rate of the tissues out of proportion to their diminished blood supply. Therefore an increased vasodilatation, undesirable though it may be in frost-bite, is appropriate here. In this way the blood supply is adequately increased to keep pace with the enhanced metabolism.

There would here seem to be a field for the cautious simultaneous use of two separate elements in treatment. (1) local application of cool air to the damaged feet; (2) measures for active local vasodilatation. A mild type of local vasodilatation could be obtained by warmth applied to the whole body while the damaged feet were simultaneously kept cool to maintain the low metabolism. The French school have practised more intense measures for obtaining vasodilatation in the affected feet: the lumbar sympathetic chain is injected with a local anaesthetic. Stricker and Buck (1940) give a detailed report of two cases in which this treatment was carried out. They claim an immediate and remarkable improvement in the damaged limb; it becomes warmer, less dusky, and much less painful. Unfortunately, in their cases they make no clear distinction between trench or immersion foot and frost-bite. It should be noted that they started their treatment one day after rescue. English opinion is at present against measures for active vasodilatation; and, indeed, the average mild case will get better with the general treatment advocated. But with really severe cases it may be worth while cautiously to try the combination suggested by these theoretical considerations. We have not yet had the opportunity. After the first few days of illness most of our patients were allowed a heat-craddle to their feet. When the pain became severe they begged for the cradle; it relieved the pain.

In cases of older people with a weakened detoxicating action of the liver it would certainly seem worth while to prevent erosion of the duodenum by placing them on a peptic ulcer regime for about a week. The parietic condition of the feet should also receive consideration: with weakened neuromuscular apparatus in the foot, there is also the danger of acute flat-foot. Patients should not be allowed to bear weight too early, and severe cases should receive faradization and special exercises to the foot muscles as a preliminary to walking.

### Summary

The syndrome of immersion foot is described. Commonly it bears a striking resemblance to peripheral neuritis.

It appears that the disease may be regarded as a massive chilling and ischaemia of all the various tissues in the foot or hand. These are successively affected in the inverse order of their biological fortitude. Thus the clinical picture may vary from a mere peripheral neuritis to the rare stage of gangrene. Most patients are rescued in the stage of skin and nerve damage. They would probably rarely survive to reach the stage of gangrene, but one case of gangrene is described.

The syndrome is in sharp contrast to that of frost-bite, in which by reason of a mechanical accident (ice-crystal formation) all tissues involved in the area suffer simultaneous death irrespective of their relative hardiness.

Treatment of the two diseases is not the same: measures for active vasodilatation are under certain circumstances indicated in immersion foot, but are dangerous in frost-bite. However, both types of lesion should be kept cool in their early stages.

Mixed forms of the two diseases are postulated.

The complication of duodenitis with duodenal haemorrhage is described. It is suggested that this may be due to the absorption of toxins from the damaged area. The similarity with Curling's duodenal ulcer in burnt patients is noted.

We wish to acknowledge the help and kindly criticism of Mr. A. H. McIndoe. Our thanks are also due to Dr. E. T. Ruston, who carried out the post-mortem examination, and to the coroner for East Surrey for his kind permission to publish extracts of the necropsy report.

## RESULTS OF EXTERNAL PROPHYLACTIC VERSION

BY

M. V. TRUBKOWITCH, M.D.

Second Obstetric-Gynaecological Clinic of the Second Moscow Medical Institute

AND

Prof. B. A. ARCHANGELSKY, M.D.

Director of the Clinic

This is a preliminary communication with the object of setting out results of prophylactic cephalic version conducted under the direction of Prof. Archangelsky in cases of breech and transverse presentations. It relates to the period 1931-41, with the majority of cases dealt with in the years 1940-1.

External version was carried out in 324 cases of breech, transverse, and oblique presentations. Of these 324 cases version was successfully performed in 293 (90.5%) and unsuccessfully in 31 (9.5%). Of the 293 successful cases 251 had been breech and 42 transverse and oblique. In somewhat under 10% of the cases either version could not be performed or, when performed, the position of the foetus relapsed into the original state. As a rule the operation was conducted in the 35th to 36th week of pregnancy, and only in 4 instances was an anaesthetic employed. In the majority of cases of successful version the desired result was obtained at the first attempt. Repeated attempts had to be made in a few isolated cases—multiparae with a small foetus and lax pendulous abdomen.

To what extent is foetal mortality reduced by the timely performance of version? Of 247 births that took place after version 3 were stillbirths (1.2%). On the other hand, among 19 cases in which version was not successful there were 2 stillbirths (10.5%). Of 228 cases in which the performance of version procured a vertex presentation there was only one stillbirth (0.44%).

Table to Illustrate the Foregoing

	No. of Births	Live Births	Stillborn
Version performed ..	247	244 (98.8%)	3 (1.2%)
" successful ..	228	227 (99.6%)	1 (0.44%)
" unsuccessful ..	19	17 (89.5%)	2 (10.5%)

### What is the Significance of External Prophylactic Version in Obstetrics?

To answer this we must examine the incidence of the various abnormal positions of the foetus. Of 107,966 births in the city of Moscow 99,552 took place at term. Of these 99,552 full-term births 96,048 (96.2%) were vertex presentations, 3,148 were breech (3.2%), and 356 cases were transverse and oblique (0.4%). Thus all non-vertex presentations provided 3.6%. Of the 96,048 head-presentation births 905 (0.94%), of the 3,148 breech presentations 318 (10.1%), and of the 356 transverse presentations 104 (29.2%) were stillborn.

	Births	Stillborn
Total number of births ..	107,966	2,048 (1.88%)
Full-term births ..	99,552	1,327 (1.32%)
Head presentation ..	96,048	905 (0.94%)
Breech ..	3,148	318 (10.1%)
Transverse and oblique ..	356	104 (29.2%)
After version ..	247	3 (1.2%)
After successful version ..	228	1 (0.44%)

It will thus be seen that successful version reduces the mortality to the level obtained in ordinary head presentation and so reduces the foetal mortality in breech presentation 10 times and in transverse or oblique presentations 25 times.

### Complications Attendant on Version

1. *Premature Labour.*—Out of 103,735 births in Moscow 7,657 (7.4%) were premature. Out of 228 cases in which version procured a head presentation at birth 2 were premature, or below 1%. This low rate is explained partly by the fact that version was done in the 36th week, a time close to full term already, and partly by the fact that version was not

performed when there were any contraindications. Obviously premature labour, where it took place, occurred before the date at which version would normally have been undertaken. All the same, the fact that only 1% of premature labour took place after version in 228 cases permits of the conclusion that version *per se* does not lead to premature labour.

2. *Haemorrhage.*—Out of 324 cases in which version was carried out only 1 case had slight haemorrhage—about 3 weeks before the onset of labour—and this had no effect on the subsequent period of pregnancy or labour.

3. *Premature Separation of the Placenta; Adherent Placenta Requiring Manual Separation.*—These conditions did not occur in any of our cases. This leads to the conclusion that external version, when all contraindications are carefully observed, does not lead to risks of haemorrhage.

4. *Premature Loss of Liquor Amnii.*—Out of all our cases this took place in about 5%. In the cases in which version was carried out premature rupture of the membranes occurred in 2%. This leads to the conclusion that the treatment exerted no influence in this direction.

5. *Prolapse of the Cord.*—Among all our clinical material this was observed in 0.4% of cases of head presentation and 2.1% of cases of breech presentation. After version which secured a head presentation this took place in 0.44%. The conclusion is reached that prolapse of the cord is not accelerated by version. On the other hand, in those cases in which a breech presentation could not be successfully turned into a head presentation prolapse of the cord took place in 11.5%.

6. *Does Version produce a More Frequent Occurrence of a Twisted Cord?*—Among all our clinical cases this was observed in 16.8%. Out of 228 cases in which version procured a head presentation at birth this was noted in 12 cases, or 5.2%.

We see, therefore, that external cephalic version does not contain any dangers provided it is carried out with due regard to indications, contraindications, and proper technique.

## Medical Memoranda

### Histiocytic Medullary Reticulosis with Transient Skin Lesions

In 1939 Bodley Scott and Robb-Smith separated from the group of diseases commonly known as "atypical Hodgkin's disease" a number of cases with such a uniform clinical and pathological picture as to suggest that they represented a distinct disease process. Histologically they showed a cellular proliferation, involving chiefly the histiocytes and their precursors, which affected the whole lympho-reticular tissue, the medullary portions of the organs being principally affected; and for these reasons "histiocytic medullary reticulosis" was suggested as a pathologically descriptive name for the disease. They reported four new cases and gave records of six others which had previously been published. The clinical picture was that of a rapidly fatal disease characterized by fever, wasting, generalized enlargement of the lymph nodes, enlargement of the liver and spleen, progressive anaemia, leucopenia, and, in some cases, purpura and jaundice. The following case, which histologically proved to be typical of this disease, showed many of these clinical features but differed in presenting a leucocytosis, which has not been previously recorded, and skin infiltrations, which had disappeared by the time the patient died.

#### CASE RECORD

A married woman aged 52 was seen in consultation with Dr. H. S. K. Lowry on Nov. 3, 1942, complaining of weakness. She had enjoyed good health apart from a rash two years previously which was thought to be pemphigus. For three and a half weeks she had been easily tired. Two weeks later she had diarrhoea and a temperature of 101°. Four days after this she developed a cough with rusty sputum. On sulphapyridine the temperature fell to normal and then gradually rose again. Two days before the consultation a tender purplish lump had appeared on the face, and this was followed by similar lesions on the trunk and limbs.

On examination her temperature was 98.6° and pulse 102. She looked ill. Her face had a yellow tinge, but there was no jaundice. The mucous membranes were pale. The skin lesions were situated on the forehead, cheeks, neck, upper chest, back, and proximal halves of arms and legs. They were raised purplish-red plaques

varying in diameter from 1/4 to 1 in., firm in consistency, and tender. The colour faded on pressure but did not completely disappear. There were enlarged soft lymph nodes in the left posterior triangle and right axilla. There was an area of impaired resonance with diminished air entry and rales in the left axilla. The liver was enlarged to 1/2 in. below the costal margin, and the tip of the spleen was just palpable. A blood count gave: erythrocytes, 3,910,000; haemoglobin, 62%; colour index, 0.8%; leucocytes, 13,400 (polymorphonuclears 10,251, lymphocytes 2,680, eosinophils nil, basophils 11, large mononuclears 469). The Paul-Bunnell test was negative, as was blood culture. The urine was normal.

The patient ran an irregular pyrexia up to 103°. Fresh skin lesions appeared during the next two days and then gradually faded and disappeared. None were visible at the time of her death. Enlarged nodes were palpable in both posterior triangles, axillae, and groins. The spleen became more easily palpable. The leucocyte count rose to 17,800 and then fell to 7,600 shortly before death. In spite of blood transfusion haemoglobin fell to 43%; she developed scurvy and oedema, and died on Nov. 30, 7½ weeks after the onset of symptoms. At no time during the illness were there petechiae or haemorrhages from mucous membranes.

**Post-mortem Examination** (Dr T. B. H. Haslett).—There was generalized enlargement of lymph nodes, more particularly those of the aortic, coeliac, and mesenteric groups. They were white and fleshy, with considerable haemorrhage into the mesenteric nodes. The spleen was enlarged, soft, and red, the increase appearing to be chiefly in the pulp, although there were a few discrete white nodules on the cut surface. The liver was fatty but otherwise normal. The lungs showed passive congestion and terminal bronchitis. The other organs were normal.

**Histological Report** (Dr A. H. T. Robb-Smith).—Section of a lymph node showed a marked proliferation in the sinus and medulla of the histiocytic elements and of atypical cells—pro-histiocytes; i.e., large cells which are polygonal in outline with nuclei rich in chromatin and prominent nucleoli. There were also zones of fibrinoid necrosis, but no obvious increase of fibrous tissue and no free iron could be observed, nor was there any proliferation of the histiocytic elements in the peri-adenoid tissue. The spleen showed a comparable picture, although the degree of necrosis was even more marked, and it had only an occasional follicle which could be made out. There was no free iron in the spleen. Both in the lymph node and in the spleen there had been phagocytosis of the red cells by the histiocytes. The liver was the least involved. There were a few perportal collections of pro-histiocytes, but the Kupfer cells, although hypertrophied, were essentially normal. The appearances throughout all the organs were typical of histiocytic medullary reticulosis.

### Pyloric Stenosis in Identical Twins

It may be generally stated that identical abnormalities in dizygotic twins are no more frequent than in brothers and sisters born singly, whereas in monozygotic twins it is the rule that abnormalities are shared. Assuming that pyloric stenosis is a congenital abnormality, the above statement should be borne out by examination of recorded cases. This appears to be so (see Table).

#### Summary of Cases of Pyloric Stenosis in Twins (O'Donnell and Klein, 1941)

	Both Affected	One Affected
Dizygotic twins (binovular) ..	2	21
Monozygotic twins (uniovular) ..	10	1 ± 1*

\* The two cases of monozygotic twins in which only one member was affected were reported by Lasch (1925) and Sheldon (1938). In both of these the type of twinning was substantiated by a description of the placenta, only one chorion being present in each case. In the former the diagnosis seems to have been somewhat in doubt, but in the latter a pyloric tumour was found at operation on the affected member. Observation of one feed only in the other twin revealed no evidence of pyloric stenosis.

#### CASE REPORT

Male twins A. C. and B. C. were born on Feb. 24, 1943. They have a normal brother aged 3. The delivery was normal, and the placenta was described as a single body with only one chorion. Both were entirely breast-fed. At four weeks A. C. started vomiting after nearly every feed, and the vomits were often projectile in character. The stools were green. He was admitted to the Hospital for Sick Children, Great Ormond Street, one week later weighing 6 lb., or 1 lb. 4 oz. below the estimated weight for age. (His brother at this time weighed 6 lb. 8 oz.) Test feeds showed that he was taking 2½ to 3 oz. per feed, given three-hourly—six in the day. On examination the ears, throat, and urine were normal. Dehydration was not evident. Observation of the abdomen during a feed showed typical "golf-ball" peristalsis, and a pyloric tumour was palpable in the right upper quadrant. Rammstedt's operation was performed by Mr. Humby under local anaesthesia and a definite tumour was found. Convalescence was uneventful, and the baby

was discharged home, gaining weight, on the fourth day after operation, returning on the eighth day for removal of stitches.

B. C. has a right inguinal hernia. He is described by his mother as "never having vomited since birth." Feeds have been watched on three occasions; visible peristalsis has been seen and a pyloric tumour felt. A barium meal was given at three months, and "a definite delay at the pylorus" was reported.

#### COMMENT

This report presents two interesting features: (1) monozygotic twins with the same congenital abnormality; (2) pyloric stenosis present in a baby without producing any symptoms.

I should like to express my indebtedness to Dr. Donald Paterson for permission to publish this memorandum.

F. L. KING LEWIS,

House-physician, Hospital for Sick Children, Great Ormond Street.

### Induction of Labour in Contracted Pelvis by Digital Separation of the Membranes

Although most obstetricians in this country are now agreed that the method of treatment of choice for cases of minor and medium degrees of contraction of the pelvic inlet in primigravidae is by "trial labour" and not by surgical induction before term, all must have been disappointed at the necessity for Caesarean section in those cases in which the "trial" failed because of the "more than average" size of the baby. Caesarean section, especially in the young primigravida, is a procedure which, if delivery per vaginam is impossible, is better avoided, as it limits the number of pregnancies to three, and, in fact, the patient often expresses a desire to be sterilized at the second operation.

The problem in these cases is to get the patient to go into labour while the baby is still small enough to pass through the pelvic brim. Simple medical induction by castor oil, quinine, and pituitary extract is only rarely successful before term, whereas surgical induction by rupturing the forewaters or even the hindwaters contraindicates Caesarean section, should the latter become necessary later on for such indications as uterine inertia or foetal distress, by reason of the risk of sepsis.

The purpose of this communication is to recommend digital separation of the membranes from the lower uterine segment, and this is performed immediately before simple medical induction is begun. Separation of the membranes has been advocated by various authorities, but, so far as I know, is not generally practised. It is carried out, I believe, in the Simpson Memorial Hospital, in Edinburgh.

In cases of pelvic contraction in which bimanual examination is being carried out at weekly intervals after the thirty-sixth week, and when it is decided that the head will just mould through the brim, digital separation of the membranes by using the index finger of the right hand is performed with the usual antiseptic precautions. The membranes are cleared for as great an area as the finger can reach when introduced through the os. Medical induction is started the same day.

During the past 18 months this method has been used in this department in suitable cases of contraction of the pelvic brim, mainly where the true conjugate diameter was between 3.25 and 3.75 in. In a series of 32 such cases in which separation of the membranes, followed by medical induction, was carried out labour failed to come on within a period of 10 days in only three. The mean weight of the babies in the cases which responded was 6 lb., labour was not long, and use of outlet forceps was necessary in only two. It may be said, therefore, that labour was induced too soon, but the striking fact is that labour can be brought on by this method in the great majority of cases after the thirty-sixth week. There was one neonatal death, occurring in the first fourteen days.

The advantages of this method are: (1) Caesarean section can be safely undertaken later in labour if necessary (it was necessary in the three cases which did not respond); (2) the membranes, being intact, serve to protect the soft head as it moulds through the brim; (3) such complications as prolapse of the cord are obviated; (4) if medical induction is begun on the same day, and is repeated every third day, labour comes on within a day or two in the great majority of cases.

I have pleasure in expressing my indebtedness to Dr. W. J. Clancy for his advice and assistance, and to Dr. Rennie, medical officer of health, and Dr. James Clark, medical superintendent, for permission to publish this communication.

## Reviews

### BODY POISE

*Body Poise.* By Walter Tinslow, M.D., F.A.C.S. (Pp. 312; illustrated. 4.50 or 25s.) Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1943.

This is an interesting monograph of particular value both to orthopaedic surgeons and to medical gymnasts. The main theme is the emphasis on the importance of scientific training in posture—i.e., a return to the principles of the older Swedish physical culture, which in recent years has been to a large extent supplanted by games, dancing, and rhythmic exercises—in remedial work.

The book contains three sections. In the first there is an account in simple language of the normal anatomy of the skeleton, joints, and muscles, described not in terms of regions but built up from the "sole of the foot to the crown of the head." This forms a good introduction to the anatomical problems of poise. The second part deals with those physical breakdowns which are characterized by muscular insufficiency, and a detailed scheme of exercises is presented for each type of disability—e.g., weak foot, flat-foot, postural defects of the spine, and so on. In the last section there is an interesting and valuable account of body poise in its special relation to games, sports, and athletics in general.

Throughout the work a full description is given of exercise schemes which have been used by the author in his practice as an orthopaedic surgeon for many years. There is also a useful account of his methods of recording deviations from normal posture. For the most part the exercise schemes, whether designed for muscle building, posture training, or correction of deformity, are of the type used by modern remedial gymnasts. Some of the exercises are admittedly difficult, and require special instruction and supervision. In postural training, for example, too little use is made of the recumbent position, which most authorities regard as an essential introduction to the final scheme in the standing position. But these are minor criticisms. The book as a whole is stimulating and authoritative, and it is a valuable addition to the departmental libraries of orthopaedic clinics and remedial exercise units.

### PSYCHOLOGICAL MEDICINE

*Manual of Psychological Medicine for Practitioners and Students.* By A. F. Tredgold, M.D., F.R.C.P., F.R.S.Ed. (Pp. 298, 18s.) London: Baillière, Tindall and Cox. 1943.

This war, like the last, has brought psychological medicine into great prominence. Men and women recruited into any of the Forces are more or less physically fit; they are on the "whole allotted to jobs within their physical capacity. Medical examination for physical fitness is more thorough than for mental stability, so that psychological breakdown for that reason alone is likely to be relatively more frequent than physical breakdown among the armed Forces in comparison with the civil population. Finally, war engenders emotion, especially the emotion of fear, to a degree unknown in peacetime, so that so-called psychosomatic disorders become common, as well as disturbances that remain essentially in the mental field.

It is no doubt under the stimulus of this situation that Dr. Tredgold, whose textbook on *Mental Deficiency* has long been a standard work of reference, has produced a convenient *Manual of Psychological Medicine*. It is, as would be expected from such a source, written clearly and readably. Its sources are eclectic and sometimes unconscious. It has some Kraepelinian imprints and others of a later date, and, as is the way with imprints, they are sometimes indistinct. The allusions to Freudian doctrine, for example, do not seem to refer on the whole to its more recent developments. The discussion of the more definitely psychogenic types of illness is superficial, especially in regard to children; but the book is intended as a general handbook and not as a work for specialists.

There are some suggestions which are perhaps in these days a little unorthodox. For example, Dr. Tredgold recommends that people with anxiety states should be put to bed as a

routine. There are some novel observations, such as that administration of strychnine, which is certainly not customary in these conditions, may drive the patient to suicide. It would be interesting to have this observation documented. Spasmodic torticollis is classed as hysterical, without further comment, the very interesting condition of anorexia nervosa is barely referred to. Confidence is expressed in the cure of traumatic neurosis by the award of a lump sum. Suicide is spoken of as a frequent outcome of obsessional neurosis, which is not a conventional opinion. A good case is made for the rehabilitation of chronic neurasthenia as a clinical concept, on constitutional basis.

The chapter on mental defect is the masterly summary that one might expect from an author whose experience is pre-eminent in this field. He gives a healthy warning, much needed in these days of the widespread use of intelligence tests, that in themselves they are quite inadequate as a gauge of social incapacity.

### RUDIMENTS OF ALLERGY

*Primer of Allergy.* By Warren T. Vaughan, M.S., M.D. Second edition (Pp. 176; illustrated. 10s.) London: Henry Kimpton. 1943.

"Tradition has it that in former times when two or three ladies were gathered together they adored talking about their operations. To-day they adore talking about their allergies. To enlighten them in such discussions on this 'strange and tantalizing state,' and to help others to understand everyday topical remarks on stage and screen, Dr. Warren Vaughan has published a *Primer of Allergy*. The doctor or consultant is regarded as the expert in strategy; it is the sufferer alone who must conduct the campaign. The primer is designed to help such sufferer to adjust himself with the utmost success to those environmental factors which contribute to his discomfort. The subject-matter is portrayed in very modernistic military mood, with a description of the enemy (allergens), the defence of the realm (methods of combating sensitization), liaison and reconnaissance (taking inventory), plan of attack (therapeutic programme), and, finally, 'victory or defeat.' Precise directions for patients suffering from each of the common allergies are set out at great length, with methods for avoiding or removing the common inhalant and food allergens, and the keeping of inhalant and food diaries—in fact everything of interest to the punctilious or scientific patient. The numerous illustrations are in cartoon fashion with a final Tom Mix-ish 'farewell to allergy.' The book will teach and help the sufferer to 'live with his allergy.'

### Notes on Books

A manual entitled *Diseases of the Ear, Nose and Throat* by Dr. DOUGLAS CARRUTHERS of Sydney will prove useful as an introduction for students to clinical work in a special department. There is no attempt to treat any part of the subject in detail, but the author is doubtless aware of the kind of information his students demand. There are, however, numerous books of similar scope with which this one enters into competition, and the senior student will in due course indicate whether or not it receives his approval and meets his requirements. A sound innovation is the inclusion of a chapter on diseases of the mouth, but it is too short, consisting of less than three pages, and the author has in the same way touched very lightly on other important subjects, especially diseases of the larynx. The feature on which he lays special emphasis is methods of examination, and in this he shows his appreciation of the chief clinical need of the student and his experience as a teacher. The book is published at 25s. by Angus and Robertson of Sydney and London.

That a textbook should require six editions in less than twelve years gives ample proof of its excellence and suitability for the purpose in view. This is what has happened to *Massage and Remedial Exercises in Medical and Surgical Conditions*, by NORTON M. TOWN (Bristol: John Wright and Sons; 25s.). The general scheme of the book is a systematic presentation of diseases arranged in accordance with the various systems of the body. A brief outline of the aetiology, symptomatology, and pathology of each disease is followed by a section on treatment, in which the physical treatment is dealt with in detail, illustrated where possible by photographs or diagrams. In the present edition the chapters on fractures have largely been rewritten to bring them up to date, otherwise no particular changes have been made. At a time when rehabilitation is in everybody's mind a book such as this must be of the utmost value, and the appearance of a new edition is very timely.

SATURDAY FEBRUARY 12 1944

## REGULATION 33B IN PRACTICE

Much is being said and written about Defence Regulation 33B which hinders a real understanding of its purpose. This regulation, which came into force just a year ago, is in itself rather misleading. It is headed "Compulsory Treatment of Venereal Disease," and, together with the rules and directions issued under it, gives detailed instructions to special practitioners and to medical officers of health on the action they are to take if a patient names or otherwise indicates the "contact"—the person whom he (or she) suspects to be the source of the infection. This information must be kept secret, and is covered by qualified privilege in case of proceedings for defamation. The special practitioner must send particulars of the patient and the contact to the medical officer of health. If one person is named as a contact by two or more patients the M.O.H. must (if the information seems reasonably probable) serve a notice on the contact to attend for examination by a special practitioner of her (or his) choosing. Failure to obey is punishable by fine, prison, or both. If the contact is found to have communicable disease the practitioner serves her with compulsory notice to be treated; and here again she may choose her own special practitioner.

The regulation has been bombarded with all kinds of adverse criticism, particularly by certain keen voluntary workers. They say it creates a class of informers; the contact is at the mercy of an unknown accuser; she may be forcibly examined on the word of two persons who may conspire to defame her with impunity; it introduces notification of venereal disease by a side wind. More reasonable is the complaint that the regulation covers such a minute class that it is practically ineffective. Its text has been analysed by lawyers, notably by Mr. N. P. Shannon,<sup>1</sup> in great detail, and this scrupulous examination has produced more criticism of a different kind. Mr. Shannon, for instance, suggests that the rules do not provide with enough certainty that the patient should be warned that his name and address will go to the medical officer of health's office if he gives information. A special practitioner, moreover, may remain responsible for the treatment of a contact by a colleague, but has no right even to be informed whether the contact is duly attending for treatment. In at least some circumstances a special practitioner may be obliged to disclose confidential information in court. Mr. D. H. Kitchin points out<sup>2</sup> that on a strict reading of the text an M.O.H. may not disclose information concerning a contact even to a member of his staff unless for the enforcement of the regulation.

All these critics have tended to lose sight of the real meaning of Regulation 33B. The elaborate and rather

repulsive procedure for compulsory examination and treatment is in fact hardly ever used. What 33B does, and is meant to do, is to help the medical officer of health to trace contacts. It ensures that he shall receive at any rate some of the information he would have if venereal disease were notifiable. He is not legally obliged to move until he has two notices affecting the same contact; but actually, in a growing number of areas, he moves on the first notice, sending a social worker to visit the contact and induce her to come and be examined. This method of informal, assiduous persuasion will do more to combat venereal disease than any other single measure. Speakers at a discussion held by the Medico-Legal Society on Oct. 28 testified that by far the most usual attitude in a suspect visited by a social worker is horror at a grim possibility which had never occurred to her, and eagerness to be cleared or cured as soon as possible. Anger, recrimination at the informer, and threats of a slander action are extremely rare. The objections to the regulation come mainly, in fact, not from the contacts but from well-meaning members of voluntary societies. The informal approach clearly does no injustice whatever to the contact, even if she has been wrongly indicated. That to facilitate it is the true object of the regulation appears from a circular recently sent out by the Ministry of Health to councils of counties and county boroughs.<sup>3</sup> The Minister, it says, takes the view that a local authority for venereal disease should, as a recognized and regular part of its work, do what is possible to trace contacts and persuade them to attend for treatment. To remove the legal barrier imposed by Defence Regulation 84, which enjoins strict secrecy until the information is used for the purposes of the regulations, the Minister is using the power Regulation 84 gives him to permit disclosure: he accordingly declares that information obtained through the operation of Regulation 33B may be disclosed so far as is necessary to enable action to be taken, in discharge of the functions of the council as a venereal disease authority, to trace contacts of persons suffering from venereal disease and to persuade them to undertake treatment. Approved additional expenditure on this work will rank for grant. The circular also observes that persons doing the work enjoy the same protection against actions for defamation as do persons acting under Regulation 33B—viz., in the absence of malice or indirect motives they are not open to such actions for anything done as part of their duty. With respect, this reassurance is not quite accurate. Qualified privilege does not prevent an aggrieved person from bringing an action; the M.O.H. or officer acting under him is still "open to" action, but of course the likelihood of one being brought is much less when the defence of qualified privilege is known to exist.

Another legal aspect of venereal disease practice ought to be considered. In at least one area the contacts are sought out from the clinic and not from the health office. The exponents of this plan aim to dispense with the 33B procedure, which they dislike, and especially with the notification to the M.O.H. of the patient's—the "informer's"—name. But the first words of the regulation lay down clearly that any special practitioner who receives from a patient information about the source of the disease must

<sup>1</sup> *Brit. J. vener. Dis.*, 1943, 19, 22, 67.<sup>2</sup> *Med. Pr.*, 1943, 705, 264.<sup>3</sup> Circular 2596, Dec. 25, 1943

unless he thinks the information has no substance) send he prescribed notice to the M.O.H. If the practitioner gets such information he is bound by law to pass it on. If the proper notice is duly sent to the M.O.H. an unofficial approach by the clinic staff is now lawful, but the terms of the regulation do not allow it to be side-tracked in any method of tracing contacts.

The numbers of patients and contacts affected by Regulation 33B are still lamentably small. Up to June 30, 1943—the latest date for which figures are available—110 contacts had been indicated by two patients each and so brought under the regulation; 71 of these were treated and 3 prosecuted for breach of notice to be examined or treated. About 1,780 other persons were indicated by one patient each, but only 220 of these were informally induced to undertake treatment. It is to be hoped that the Minister's information is incomplete, and that the numbers have risen during the considerable interval that has elapsed since these figures were compiled; but the reply given on Jan. 20 and reported in last week's Parliamentary Notes at page 203 adds little to our knowledge.

Perhaps as workers against venereal disease realize that 33B is meant to help them, and that its "manifest content" really matters very little, they will cease to be afraid of the bogeys that their imaginations, with assistance from legal commentators, have conjured up, and will make more use of it. The truth is that 33B belongs to a class of law that was once unknown in this country but has now come, without attracting much attention, to occupy a definite place in our legal system, and a place which will certainly become more and more important. This is administrative law: it expresses a theoretical or contingent purpose while designed to fulfil an ulterior practical one. The growing complications of life brought it forth, and the country's danger has immensely quickened its growth. No robust Earl of Halsbury now sits to challenge the rising tide; the courts' concern is to give the Executive every support and encouragement. Safeguard against abuse of power is now rather to be found in an informed and vigilant public opinion, to which Ministers are fortunately very sensitive. Venereal disease workers and others would do better to realize that administrative law has come to stay, study its uses, and work with it as loyally as possible.

## CARBON TETRACHLORIDE AND THE LIVER

The lethal effects of carbon tetrachloride, in both men and animals, have long been known to be associated with cellular damage of the liver and kidneys, but a feature which surprised the earlier investigators was the rapidity with which regeneration took place in non-lethal cases. Carbon tetrachloride in repeated sublethal doses was, comparatively speaking, also found to have remarkably low toxicity for a substance at one time regarded as the most dangerous of modern industrial solvents. More recent investigations have helped to clear up the mystery and to confirm the view that, although carbon tetrachloride is an industrial hazard liable to cause temporary disablement and severe discomfort, the rapid and disagreeable effects to which it gives rise provide some safe-

guard against permanent damage from repeated sublethal dosage. Even in cases of acute poisoning by ingestion the actual damage is apparently more a disturbance of metabolism than destruction of tissue, and can be prevented from becoming fatal if suitable measures are taken in time. Repeated non-lethal exposures, sufficient to cause more or less severe disturbances of health at the time, leave no permanent ill effect if the interval between them is long enough to allow regeneration. This view is supported by the results of two separate investigations—of one case of acute poisoning, and of a series of cases of chronic poisoning with gastro-intestinal and mental symptoms after repeated inhalations of high concentrations.

Since animal experiments have shown that the essential tissue damage in severe carbon tetrachloride poisoning is acute hepatic necrosis and acute nephritis, it might be expected that symptoms of poisoning in human beings would be associated with evidence of such damage, as revealed by liver-function tests and urinary analysis. The outstanding feature of subacute and chronic hepatitis is shown by Higgins and his co-workers in a paper appearing elsewhere in this issue to be a disturbance of the plasma proteins. A fall of serum albumin below 2 g. per 100 c.cm. is of grave significance, while a rise in globulin is common in all varieties of hepatitis and a persistent alteration of the albumin/globulin ratio indicates irreparable damage. In subacute hepatitis a moderate rise in serum bilirubin and phosphatase is accompanied by striking changes in the plasma proteins and a gross reduction in the laevulose tolerance. Yet in a case described by Beattie and his co-workers in our opening pages, in which acute carbon tetrachloride poisoning followed accidental ingestion of 30 to 40 ml., the only significant abnormality as shown by liver-function tests was a rise in serum bilirubin during the acute phase, although the liver enlarged rapidly. Urinary tests for albumin, sugar, bile, and urobilinogen were also negative, except for a transient appearance of urobilinogen during a relapse. The successful treatment of this case by methionine, as an intravenous infusion with a papain-trypsin digest of casein, gave further opportunity to investigate the nature of the liver damage. An attempt was made to follow the mode of action of methionine by estimating the nitrogen and sulphur balances of the patient and by determining the partition of the urinary sulphur between the oxidized (total sulphate) and unoxidized (neutral) fractions. The nitrogen balance was negative during the first two days and positive during the next two. The patient also excreted an excessive amount of unoxidized sulphur during the first two days. The suggestion is made, therefore, that during the acute phase protein synthesis in the liver was disturbed, but that this disturbance was in the nature of a metabolic derangement rather than due to an actual destruction of liver substance.

Absence of actual hepatic injury from repeated though less severe exposure has also been demonstrated in an investigation by Stewart and Witts<sup>1</sup> of a series of cases of "chronic" carbon tetrachloride intoxication in a factory where high concentrations of carbon tetrachloride in the atmosphere were apt to occur from spillage and leak-

<sup>1</sup> Brit. J. Indust. Med., 1944, 1, 11.

age. A large number of workers had complained of symptoms which could be sharply divided into two groups: gastro-intestinal and cerebral. Nausea, vomiting, colic, and diarrhoea were the prominent features of the gastro-intestinal disturbance, but were quickly relieved by a brief period of absence from work; and in spite of recurrent episodes there was no continuous deterioration in health. Giddiness, vertigo, acute and chronic headaches, drowsiness, alteration of the sleep rhythm, and mental hebetude characterized the cerebral effects, but these also disappeared with surprising rapidity on removal from exposure. Even in the cases with most severe gastro-intestinal disturbance—which earlier writers considered to reflect an early stage of liver damage—the blood urea, serum bilirubin and phosphatase, and the plasma proteins were all within normal limits; and the Takata-Ara reaction was negative throughout. Five cases of albuminuria had occurred among the exposed workers, but in the three eventually traced and re-examined this was not accompanied by other evidence of progressive renal disease. Radiographic and gastroscopic examination revealed hypertonicity, irregular peristalsis, and spasmodic contraction of the stomach and intestines, and hyperchlorhydria was found in more than 50% of the cases examined. It is suggested, therefore, that both the cerebral symptoms and the gastro-intestinal disturbance, bearing a strong resemblance to post-anaesthetic sickness, are the result not of liver damage but of the narcotic action of carbon tetrachloride on the cerebral cortex, as shown by mental hebetude, and of a stimulant action on the parasympathetic, or inhibition of the sympathetic, centres in the hypothalamus, as shown by the gastro-intestinal symptoms. This view of the mechanism of action of  $\text{CCl}_4$  is not identical with the methionine hypothesis put forward by Beattie, but both investigations bring out very clearly the fact that to cause permanent liver damage the immediate toxic action of exposure to carbon tetrachloride must be repeated at short intervals. If death can be prevented by suitable treatment, as in Beattie's case, or if the dose is too small to produce definite changes in the liver, repeated exposure at long enough intervals will not cause hepatic injury. But in animals, at least, central necrosis of the liver, reversible for a time, may be followed by irreversible cirrhosis if the dosage is repeated often enough. It would therefore seem wise to ensure that, in factories where exposure for any reason cannot be prevented, the "sufficiently long interval" between exposures of workers should be achieved by alternation of work whenever symptoms appear.

### STATISTICS OF INCAPACITATING ILLNESS IN CANADA

The reports on incapacitating sickness among the insured population, issued by the Health Department of Scotland for the seven years from mid-1930 to mid-1937, are well known; but, owing to the publications being less accessible, few people in this country can yet have seen the Statistical Studies of Illness in the Civil Service of Canada for the fiscal years 1936-7, 1937-8, and 1938-9, which were published in 1939 and 1940. These studies of morbidity began in 1934, and embraced the numbers of working days lost owing to illness and accidents in a population of some 35,000 civil servants, including outdoor workers connected with mining, agriculture, fisheries, and postal ser-

vices. At the beginning of this work no standard code of diseases for morbidity, as distinct from mortality, was available, but the preparation of a code which could readily be correlated with the International List of Causes of Death was stimulated by studies in progress at that time of the records of pensioners from the war of 1914-18 (eventually published in 1939). The outcome was the completion of a Standard Morbidity Code for Canada, based upon the 4th revision of the International List (1929) and issued by the Ministry of Pensions and National Health in 1940. This code had been accepted as standard in Canada as early as 1936, and an index to it was prepared under the direction of Mr. J. T. Marshall, at that time in charge of the vital statistics of British Columbia and now Chief of Vital Statistics for Canada. It was employed for the Civil Service studies referred to above and is also being used in the classification of Army and pensions records in the present war. The U.S. Public Health Code, and the Medical Research Council's code in this country, are based upon the latest revision of the International List (1938), but most of the disease sections can be correlated with the Canadian code without difficulty, though the classifications of injuries will not be so easy to relate.

The Civil Service tabulations provide records over three consecutive years of the numbers of persons ill, numbers of illnesses, total days lost, and average days lost per illness from each important disease group in a population which varied little from 35,000 and included some 5,700 women. The time lost by certified illness of all kinds averaged 5.9, 5.7, and 5.9 days per person in the years 1936-7, 1937-8, 1938-9 respectively. Sick leave without certificate is allowed for three days or less at a time, up to an annual total of eight days, and such absence can be included only in the all-causes totals; in the three years it averaged 1.6, 1.4, and 1.7 days per person. Among the many diseases distinguished, "influenza" was the largest single cause of certified illness, being responsible for 33, 18, and 29% of illnesses in the three years, and for 18, 9, and 16% of the total days lost. For the respiratory type the average durations of sick leave were 11, 8, and 10 days, and for other types 8, 8, and 11 days. Approximately 2 per 1,000 of the population were absent during each year as a result of tuberculosis. "Rheumatism" showed a steady rise with increasing age as regards both incidence and time lost; for males in 1936-7 the incidence rate was 32 per 1,000 at ages 60-64, compared with 7 at 25-29.

It is impossible in a short note to do more than refer to a few of the points of interest revealed by these careful tabulations, which will provide research workers in this field with a compendium of information for many years to come. Perhaps we may hope for similar analyses of sickness records in some large industrial groups in this country after the war, if not indeed from our own Civil Service. The importance of employing the M.R.C. code as basis for all such studies to be undertaken here, so that they may be comparable as regards nomenclature at least, hardly needs emphasis.

### BREAST-FEEDING

In 1942 the Minister of Health appointed an Advisory Committee on Mothers and Young Children, and at an early meeting a Health Campaigns Subcommittee was asked to consider what could be done to intensify the effort to secure more breast-feeding of infants. A report of this committee has now been published.<sup>1</sup> The subject-matter deals with the incidence of breast-feeding and its failure, with the arguments in favour of breast-feeding.

<sup>1</sup> Ministry of Health: Reports on Public Health and Medical Subjects. No. 91, *The Breast-feeding of Infants*, H.M. Stationery Office. (4s.)

and with recommendations. That there is need for more research into the physiological problems of lactation and that there should be better instruction of medical students, nurses, and midwives will be generally agreed. Improved statistical returns and propaganda through the B.B.C., women's journals, and educational films are also recommendations which can be readily accepted. It is also urged that paediatricians "or other medical officers specially interested in babies"—a phrase which might have been worded better to indicate the need for special experience—should be appointed to maternity wards or hospitals. The management of babies in such units is also considered, and alongside a plea for restricting the use of bottle-feeding was a recommendation for more elasticity in the whole routine of infant management. It is here perhaps that some doubts will arise. In a section on the paucity of statistical material the report refuses to consider the results obtained in "foreign countries," but if this means that they failed to take a look at New Zealand it is unfortunate. Whatever criticisms may be offered of the "Truby King system," it is generally admitted that for breast-feeding it is supremely successful, and it is fair to summarize it by saying that it largely substitutes detailed routine for the type of irregularity and slipshod methods that are certainly elastic. The subcommittee has apparently obtained a lot of evidence, some of which is reproduced, but its composition (two doctors out of eight members) does not carry complete confidence that the evidence has been satisfactorily probed and sifted. For example, there is a brief section in the report dealing with lamb dysentery and its prevention by early breast-feeding after immunization of the ewe. But this fact is recorded without any reference to the difference in placental structure in the different animal species and the varying importance of trans-placental and transmammary transmission of immune bodies. In other words, while the recommendations are for the most part admirable, the body of the report contains material which is distinctly superficial and is, in fact, to some extent not suitable for consideration either by the subcommittee or by the main committee, which appears to contain nine medical practitioners out of a total of 30. For such a committee to state that medical students are "taught a number of shibboleths about breast-feeding" is surely going far beyond the terms of reference, and it is probably inaccurate to infer as a result of interviews with medical students "from some of the big teaching hospitals" that attendance at an infant welfare clinic is never compulsory. Methods to increase the breast-feeding of infants are undoubtedly necessary, and the report indicates clear ways in which such methods can be at once developed; but it also touches on technical matters which does not appear to be capable of dealing with.

#### THE MEDICAL TECHNICIAN

We have received from the Association of Scientific Workers a memorandum on "The Problems of the Technician in Medical Laboratories": the latter term includes "hospital laboratories, industrial laboratories producing medical products, university laboratories of anatomy, physiology, biochemistry, pathology, bacteriology, etc., and laboratories of medical research institutes." It is first pointed out that this type of worker is at a disadvantage from two points of view: he cannot obtain a university degree in his subject by spare-time work, as workers may in other kinds of scientific laboratory, and his experience may not fit him for service in other spheres. It is therefore all the more important that his status should be defined and assured, and that conditions in this calling should attract and retain the right type

of entrant. This memorandum makes general proposals to these ends, of which the more important are that there should be a regular system of training, a recognized qualification, and a recognized salary scale. With the first of these proposals there can be no disagreement: all junior technicians should be given the opportunity of training for higher posts, both by enabling them to attend courses of instruction in polytechnics or elsewhere and by systematic instruction from seniors in their own departments. A qualification presents greater difficulties: there are several such already, notably the diploma of the Institute of Medical Laboratory Technology, formerly known as the 'Pathological and Bacteriological Laboratory Assistants' Association. It is suggested here that this diploma might continue to be the recognized qualification for technicians in clinical laboratories, but that the ideal to aim at for medical technicians generally is a university diploma. This proposition and that of "encouraging part authorship of publications of scientific work in which the technician has made a constructive contribution apart from purely technical assistance" both appear to envisage a generally higher status than is now everywhere recognized. An adequate and more or less standard scale of remuneration is much to be desired: present rates vary widely, and it is no secret that valuable technicians often leave the laboratories which have trained them to enter a service where the rates of pay are much higher. We wish success to any effort aimed at bringing these things about, but more specific proposals will be necessary before anything can actually be done. It will also have to be decided first whether workers in laboratories of so many different kinds should be catered for in one scheme. There is little in common between work in an anatomy department, a clinical laboratory, a serum institute, and a factory turning out endocrine products, and no unified scheme of training and qualification can cover all the specialized types of laboratory work connected with medicine. There is something indeed to be said for having separate organizations caring for the interests of technicians in the academic, clinical, and commercial spheres.

#### A NEW SYNTHETIC OESTROGEN

A new series of synthetic oestrogens has been discovered in America by Blanchard, Stuart, and Tallmann.<sup>1</sup> The most active is 2:4-di-(*p*-hydroxyphenyl)-3-ethyl hexane, with a laboratory number of 118B, and now known as "octofollin." The authors rightly point out that this compound is not chemically related either to the natural oestrogens or to those of the stilboestrol series. Actually it is not very different from hexoestrol, the chief difference being that the two carbon atoms to which the phenyl groups are attached are not adjacent as in hexoestrol but are separated by a carbon atom to which an ethyl group is attached. It is interesting that the formula of octofollin cannot be arranged on paper to look like that of the natural oestrogens. Some of the new series can, but they are much less active. This emphasizes the fact, already well known to organic chemists, that the two-dimensional similarity between the skeletal structures of stilboestrol and the natural oestrogens is fortuitous, and has no basis in three-dimensional reality.

Clinical reports of the activity of the new compound are now appearing. Freed and his colleagues<sup>2</sup> found that daily doses of 1 to 5 mg. by mouth gave symptomatic relief to the majority of 35 menopausal women, three of them complaining of nausea or vomiting. Hufford<sup>3</sup> was unable to

<sup>1</sup> *Endocrinology*, 1943, 32, 307.  
<sup>2</sup> *J. clin. Endocrinol.*, 1942, 2, 213.  
<sup>3</sup> *J. Amer. med. Ass.*, 1943, 123, 259.

produce such relief with daily doses of 1 mg. by mouth, but 2 to 5 mg. twice a week intramuscularly proved to be beneficial in 21 cases of surgical and natural menopause. There was no gastro-intestinal disturbance. The question of dosage was gone into in some detail by Roberts, Loeffel, and MacBryde,<sup>4</sup> who showed that even doses of 5 mg. a day only partly relieved symptoms in 50% of the cases, and that the results were not much better when doses of 15 mg. were given daily for 14-day periods with 14-day rests. These and even higher doses did not give rise to nausea or vomiting in any of their 44 patients, nor could any effect on liver function, blood, or urine be demonstrated. These authors point out that octofollin is weight for weight more expensive than stilboestrol, and 5 to 10 times less active. The advantages they claim for it are the absence of gastro-intestinal side-effects and—of theoretical interest—the fact that it does not produce leucocytosis, thrombocytopenia, or death in dogs so readily as do stilboestrol and oestradiol when administered in vast doses.

The nausea and vomiting from stilboestrol are still a vexed question. These symptoms seem to be more prevalent among American than among British patients. It cannot be too often stressed that oestrogens of the stilboestrol series are extremely active, and the doses employed are very often unnecessarily high. Stilboestrol can be obtained in tablets ranging from 0.1 mg. to 5 mg., and it is possible that an even smaller tablet should be made available. Certainly tablets of 0.1 mg. provide an ample dosage in a large number of cases. The occasional nausea and vomiting may often be overcome by lowering the dose, and cannot be attributed to any chemical property of stilboestrol *per se*, since Greene<sup>5</sup> has shown that large doses of an ester of oestradiol (oestradiol carboxylate) cause similar symptoms. It appears that nausea and vomiting and excessive oestrogen dosage go together. The absence of these symptoms in treatment with octofollin is probably due to its relative inactivity: clinicians start off with a dose that is too low and have to increase it so that adequate dosage is reached with minimal amounts of the compound. The procedure with stilboestrol is usually the other way round. The observation of Roberts and his colleagues that even in their cases successfully treated with octofollin objective signs of oestrogenic action were still lacking, in that not one of them developed an oestrous vaginal smear, shows that the dosage was indeed minimal. If symptomatic relief is attained without the production of an oestrous smear it is further evidence that stilboestrol dosage is usually too high. Taken all in all, the new compound is of theoretical interest, but its practical advantages remain to be proved.

### TRAINING NATIVE DOCTORS IN THE PACIFIC

A recent visitor to this country has been Dr. V. W. T. McGusty, Director of Medical Services, Fiji, who spoke at a London conference on developments in the training of native doctors and nurses for work in the Pacific area. Dr. McGusty, who went out to Fiji in 1912, is the head of the Central Medical and Nursing Schools at Suva, which were visited by some members of the B.M.A. during the world tour eight years ago. To appreciate the work done by the school it is necessary to bear in mind the historical background. When Fiji was opened up to white traders and settlers infectious diseases, including a virulent form of measles, and also tuberculosis, were introduced, and the population steadily declined for many years, reaching its lowest point in 1919; then it began to rise again and is still increasing. The greatest danger of the early days—the seventies of the last century—was smallpox, and Sir William MacGregor, who was chief medical officer in

Fiji at that time, imposed a quarantine and resolved to have the whole population vaccinated. As vaccinators be used young Fijians, who, after instruction, carried out the work so well that it was decided to make more use of them, and they became dispensers in the hospitals and carried out a service as medical auxiliaries. They were the forerunners of the native doctors of the archipelago to-day. In 1910 a system of training Fijian nurses was introduced, and there is now at Suva a nursing school with 100 pupils. The standard of the diploma is not equal to that of the State-registered nurse in this country, but that is because the general school education has not provided the native with sufficient educational background. The same is true of the native doctor. After the last war the International Health Division of the Rockefeller Foundation provided funds which enabled the Central Medical School at Suva in 1928 to open its doors to students from all the British administrations of the Western Pacific—Western Samoa, Cook Islands, Tonga, Gilbert and Ellice, and the Solomons, also from the condominium of the New Hebrides, and some Maoris from New Zealand. All the staff of the Suva hospital are teachers in the school, where the native students are given a four-years course in medicine, surgery, and public health. On qualifying they receive a restricted registration, having force only in the islands of the Pacific. These native doctors are not normally allowed to practise except as members of the Government service, which appears to give them the opportunity of a useful career. They provide a type of medical service within the economic capacity of the rather impoverished Fijian administration, and it is an advantage that they are of the social class of the natives themselves. The number of students in the medical school at any one time has hitherto been about 46, but it is to be increased to 76, including 8 dental students. Some of the Suva-trained doctors are already running their own hospitals. One Fijian native doctor has taken the full qualification at New Zealand University (entitling him to practise without the geographical limitation) and another is in training.

### THROMBOSIS OF CENTRAL RETINAL VEIN

Since Holman and Ploman reported favourably in 1938 on the use of heparin in thrombosis of the central vein of the retina this drug has been tried out in cases of what is generally a progressive condition. The condition, however, is relatively rare. Huggett and Juler<sup>1</sup> reported in 1942 on 7 cases and Rosengren and Stenström<sup>2</sup> have given their experience with 30 cases. Neither report bears out the early hopes; good results are exceptional. In an analysis of end-results in 32 untreated cases Huggett and Juler find that such little improvement as they noted in their 7 treated cases is paralleled by those untreated, and they stress that the administration of heparin is not without risk. Rosengren and Stenström observed improvement immediately after treatment in 21 of their cases, but this was not maintained when the patients were re-examined. These results—and early treatment does not seem to influence them materially—bear out the belief that what passes clinically as thrombosis of the central vein of the retina is frequently a blocking of the vein from intimal proliferation.

Dr. Arthur Harold Gale will deliver the Milroy Lectures before the Royal College of Physicians of London on Tuesday, Feb. 22, and Thursday, Feb. 24, at 4 p.m. at the College, Pall Mall East. Subject: "A century of changes in the mortality and incidence of the principal infections which cause death or disability in childhood."

## DIPLOMA IN PHYSICAL MEDICINE

*Regulations by English Conjoint Board*

Paragraph 7 of E.M.S. Memorandum No. 6, on "The Organization of a Hospital Rehabilitation Department," issued by the Ministry of Health, reads: "Wherever possible, it is desirable that the various activities connected with rehabilitation should be under the personal supervision of a single member of the medical staff, whose duties include the maintenance of general oversight of the exercises, etc., given to patients, the prompt examination of anyone complaining of pain or other unfavourable reaction, and the holding of regular conferences with members of the rehabilitation staff. Such supervision is essential to success, and in no sense interferes with the continuity of control exercised over the individual patient by the original physician, surgeon, or obstetrician who orders rehabilitation therapy, and with whom the medical supervisor works in close association."

In this connexion it may be noted that the Conjoint Board in England has recently published the regulations for a Diploma in Physical Medicine granted jointly by the Royal College of Physicians of London and the Royal College of Surgeons of England (D.Phys. Med., R.C.P.&S.Eng.). These regulations, copies of which may be had post free from the Secretary, Examination Hall, 8, Queen Square, W.C.1, provide that (a) the examination is open to practitioners of not less than three years' standing who have held recognized hospital appointments and have completed a course of full-time special study extending over twelve months; and (b) the whole examination, which is divided into two parts, must be taken in the first instance, and subsequent admission to Part II is, of course, dependent on success in Part I. A syllabus indicating the scope of the examination is published in the regulations.

Since there may be some candidates whose experience, either in one of the Services or in the E.M.S., during the last three or four years may have been sufficient to justify their admission to the examination under the provisions of Regulation 6, arrangements are being made to conduct the examination for the first time in July next. Applications for admission to the examination under these provisions must be accompanied by original certificates (which will be returned), setting out the experience on which the application is based, and must reach the Secretary not later than Friday, June 16. The fee should not be forwarded until notification is received that the application has been approved and admission to the examination granted.

## AFTER-CARE OF SERVICE PSYCHIATRIC PATIENTS

A scheme of after-care for men and women invalided out of the Services on account of psychiatric disabilities is announced by the Board of Control. The Service Departments and the Ministries of Health, Pensions, and Labour have co-operated in drawing up the scheme, and the organization of the work in England and Wales is to be undertaken by the Provisional National Council for Mental Health in collaboration with the Mental After-Care Association. The scheme will cover neurotics, psychoneurotics, and psychotics who no longer require in-patient treatment but who need further medical treatment and advice or help in finding employment or in adjusting themselves to civilian life. Officers commanding Service psychiatric hospitals and establishments and the medical superintendents of E.M.S. Neurosis Centres will notify the Board of any patient about to be discharged from the Services and returning to an address in England or Wales who needs after-care and is willing to receive it. This notification, accompanied by a report from a trained social worker allocated to each of the hospitals and centres by the Provisional National Council, will be forwarded by the Board to the P.N.C. to be dealt with by the latter's regional social worker. This officer will visit the patient at home and take any further steps necessary, acting in co-operation with the patient's own doctor and the local authorities and Government Departments concerned. A scheme on similar lines is being organized by the General Board of Control in Scotland, and one is under consideration for Northern Ireland.

The first series of scholarships for nurses which the Hospital Saving Association is providing out of its 21st birthday funds (July 31, 1943, p. 147) will consist of two scholarships for nurse dicticians of approximately £250 each; four for nurse teachers of £200 each; four for health visitors of £105 each; twelve for industrial nurses of £65 each; and four for midwife teachers of £75 each. They will be awarded annually over the next four years, will be open to nurses who are on the general part of the State register and have trained in hospitals within the area of King Edward's Hospital Fund, and will be available at any of the recognized training centres. Candidates will be required to sit for a competitive examination. Application forms may be obtained from the Royal College of Nursing, 1a, Henrietta Place, Cavendish Square, W.1.

## Reports of Societies

## PHYSIOLOGY OF FAINTING

At a meeting of the Section of Anatomy and Physiology of the Royal Academy of Medicine in Ireland in Dublin last November, with the president of the section, Prof. E. J. CONWAY, in the chair, H. BARCROFT, O. G. EDHOLM, J. MCMICHAEL, and E. P. SHARPEY-SCHAFER presented a paper on changes in the circulation during fainting.

At the onset of fainting, it was observed, the heart slowed and the blood pressure fell steeply to a low level. Measurement of the cardiac output by the direct Fick method in seven subjects showed that during fainting cardiac output was not further diminished and might increase. The fall of blood pressure was therefore not of cardiac origin, but was due to vasodilatation. In a further investigation of the effects of a controlled haemorrhage of approximately three-quarters of a litre, three subjects fainted while the forearm blood flow was being recorded by the Lewis Grant plethysmographic method. In all cases forearm flow increased during fainting. The combination of increased forearm flow and fall in blood pressure signified marked vasodilatation in the forearm during fainting. In view of the intense pallor of the skin the site of the vasodilatation was likely to be in the skeletal muscle.

In another series of experiments the effect of sympathectomy was produced by anaesthetizing the deep nerves to the forearm musculature. There was a high initial blood flow, as all vasoconstrictor impulses were removed. During fainting the blood flow fell steeply with the descent of the blood pressure, and recovered as the blood pressure rose. It was concluded that the fall of blood pressure in fainting was due to a peripheral vasodilatation of muscle vessels, and that the dilatation was of nervous origin.

## Nerves in Joints

Prof. M. A. MACCONAILL, in a paper on nerves in joints, said that the following conclusions appeared to be justified by the results of the methylene-blue technique of G. Weddell:

1. The synovial membrane is everywhere a sensitive membrane, but not one with so high a degree of localization as the skin.
2. Both pain and phasic sensations are subserved by the intra-articular structures, including the menisci.
3. The fatty pads (Haversian glands) are structurally fit to act as manometers of intra-articular pressure, in addition to their function as stream-lining elements of the joint cavity.
4. The arterial vessels, especially those of the fatty pads, have a liberal nerve supply, including adventitial nerves; this supply ceases at the capillary level.
5. The nerve-endings observed were of the non-encapsulated type only, even those on the special ligaments. Musculo-tendinous endings of the Golgi-Mazzoni kind were, on the contrary, seen at the musculo-capsular junctions of the extensor genu muscles.

## SQUINT

At a meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health in January, with the President, Dr. MARJORIE BACK, in the chair, Mr. C. L. GIMBLETT spoke on squint, and Miss IRVINE, senior orthoptist, R.A.F., demonstrated the synoptophore.

Mr. Gimblett showed how the various theories concerning the cause of squint could not be made to fit in with the facts until binocular vision was taken into consideration. Mr. Claude Worth had discovered three stages of binocular vision in the squinting child: (1) simultaneous perception; (2) fusion; (3) stereoscopic vision. In answer to questions Mr. Gimblett said that all cases of squint were not suitable for orthoptic treatment. Rest periods were given at suitable intervals, but the young child was not discharged from the orthoptic department until he could read and be trained to accommodate properly. The ideal age for orthoptic treatment was 5 to 8 years, but a child should be sent for examination as soon as the squint was noticed. Any error of refraction should be corrected and amblyopia prevented. If the squint was neglected for two or three years, then much of the time spent in the orthoptic department would be taken up in improving vision in the amblyopic eye. Vision in the worse eye must be at least 6/12 before orthoptic treatment could be started.

## Correspondence

### Dietary Injury of the Liver

SIR.—We have read with interest in your issue of Jan. 29 the article by Dr. Joseph Gillman entitled "Effects on Rats of Prolonged Feeding with the Staple African Diet." Dr. Gillman reports that rats given a diet of maize meal and sour milk develop a "nodular cirrhosis" of the liver, which usually involves the left lobes of the organ. We have produced a similar lesion by means of diet. The lesion in question, however, is not a cirrhosis in the strict sense of portal cirrhosis; it is the condition of nodular hyperplasia, and it is the sequel to massive hepatic necrosis. In our animals we have produced every stage of the lesion from acute yellow atrophy through post-necrotic scarring to nodular hyperplasia. We have been able to show that this massive hepatic necrosis, with its sequel of nodular hyperplasia, is a deficiency disease due to lack of a constituent of protein, and that according to the degree of deficiency the condition involves the whole organ or only the left lobes. The experimental results giving the proof of this statement are now in the press and will be published shortly. —We are, etc.,

H. P. HIMS WORTH.  
L. E. GLYNN.

U.C.H. Medical School, London, W.C.1

### Research in Ophthalmology

SIR.—Because of its essential truth no critical reply to your admirable annotation on research in ophthalmology appeared to be called for. At the same time there is much to be said on the issues raised by Mr. Lionel Green (Jan. 29, p. 158). These are research, the conditions of hospital appointments, and postgraduate training. He advocates the creation of a central co-ordinating institution, and many ophthalmic surgeons who have given consideration to these matters will agree that an active voluntary body of this nature would be of great value. The practical application of basic research is seldom found within a decade, and may meet violent opposition from vested professional interests. Even in clinical matters progress may be slow—for example, squint has been treated with stereoscopic devices for over a hundred years and the term "orthophthalmic practice" was applied to this form of treatment in 1841. The orthoptic board came into being some ninety years later.

Much basic ophthalmic research has been carried out during the past decade in this country, but not by clinicians. If the approval of this state of affairs had been only tacit, it is unlikely that during the period foundations designed to remedy the defect would have been established in Edinburgh, Glasgow, London, and Oxford. In each case close collaboration is maintained with hospitals and laboratories, and already from these areas the output of work is notably increasing. Some of this research is referred to in your leading article. These foundations are not restricted in nature and they are not isolated. More than a genuine interest in the academic side is required before the clinical ophthalmologist is likely to contribute anything to basic ophthalmic research. The combination of qualities required is not a common one. To give one example, all over the world a few clinical observers are anxiously awaiting the discovery of a sex-linked blood group. The response of medical ophthalmic practitioners to such a discovery would not be an immediate one. It might take at least a decade before they would realize its significance. There is nothing derogatory in this; it means that basic observations have a different appeal to different types of observer.

Most specialties in this country have historical associations with one or other of the Royal Corporations. In ophthalmology the recognition of the M.R.C.P. for responsible appointments in London would be a practicable step which might meet some of the difficulties. The position is rather different in Scotland, where greater weight is attached to university qualifications than is the case in England. The statutory recognition of exclusive specialist bodies within the medical profession is not likely, and would tend to perpetuate rather than diminish the very real disabilities to which attention has been drawn by

your correspondent. There is a branch of medicine devoted to ophthalmology, but I hope that this will never become an "ophthalmic profession."

The present position regarding all higher qualifications is, of course, at present under review. It is certainly confusing. The young ophthalmologist can take at least three diplomas in ophthalmology and three surgical fellowships with his specialty as a part of the examination. The majority collect only those which are necessary for the areas in which they propose to practise. If the younger men are not correctly advised, much time may be wasted and unhappiness arise. A similar position may occur in other branches of medicine, and might be greatly improved by the creation of a common conjoint examining board of all the bodies concerned in granting such diplomas, with a system of exchange examinations. This would ultimately lead to uniformity, and the candidate could attain either fellowship or membership standard. —I am, etc.,

University of Glasgow.

W. J. B. RIDDELL.

### Qualities and Limitations of Proflavine

SIR.—I have been much interested in recent discussions upon the use of proflavine in the treatment of wounds. There has been a good deal of adverse criticism of it, which I believe is due to a misunderstanding of the limitations of this most useful and non-irritating antiseptic.

I have used proflavine very extensively over many years—both in hospital and in private practice—ever since it was first brought to my notice by Prof. Carl Browning, the discoverer of proflavine and at that time professor of pathology at the Middlesex Hospital. I speedily found it by far the most efficient and satisfactory antiseptic I had ever come across, and I came to use it as a routine dressing in all ophthalmic operations, its great value lying in its strong bactericidal qualities coupled with its being completely painless and non-irritating. I always used it in a strength not exceeding 1 in 2,000, and this solution was sprinkled freely upon the gamgee dressing, while on completion of the operation I always freely doused the eye with the solution before applying the dressing. By this simple method it was possible to avoid with certainty that bugbear of ophthalmic operations—viz., contamination from the lash area. One can use a solution of 1 in 1,000 with equal safety, but as I experienced ample protection with the weaker strength I preferred the latter.

Proflavine, however, has very pronounced limitations. In the first place it is purely an antiseptic in the true sense of the word, and is not a remedy to employ when infection is already obviously present. Thus it is a bad drug to use in acute purulent or semi-purulent inflammations, because it has little or no penetrative power. Moreover, its usefulness is not in a direct ratio with the strength of the solution employed; on the contrary, I found that no advantage was gained by using solutions stronger than 1 in 1,000, and, in fact, even at that concentration it was liable, if used continuously over more than a very short period, to inhibit the healing of a wound. In a still stronger solution I can well believe it becomes increasingly unsatisfactory, and its combination as a powder with sulphathiazole, which has been tried with very unsatisfactory results, is entirely contraindicated. In short, proflavine cannot be surpassed when the object is to prevent contamination from an outside source, but is inferior to other remedies when one has to deal with any widespread infection already present.

As regards the value of acriflavine as compared with proflavine, I formed a very definite impression that while acriflavine is just as efficacious in its antiseptic properties as proflavine, it is apt sometimes to cause irritation, which proflavine never does when used as I have suggested. —I am, etc.,

London, W.1.

ARNOLD LAWSON.

### Suprapubic Cystostomy in Bladder Paralysis

SIR.—In spite of the teaching of the majority of urologists there are still surgeons who advocate the tied-in catheter instead of an early suprapubic cystostomy for the treatment of the paralysed bladder. The authors of an article on fractures of the spine published in a recent issue of an important journal of surgery show such a lack of knowledge of the dangers of

how he treads in future, or he may lose an intervertebral disk. One wonders how many doctors and orthopaedic surgeons with sciatica would sacrifice a disk.—I am, etc.,

Rotherham.

ERIC COLDREY.

SIR,—The analogy between shingles and sciatica is too close to exclude the possibility of both these conditions being akin. By sciatica I mean the sudden crippling pain along the course of the sciatic nerve which goes after a week or two "on the club," from which the patient recovers totally, whether assisted by our remedies or not, but in which the pain is acute enough to need a pain-killer, at times even morphine injections. This sciatic pain comes on suddenly; often the patient complains of a "chill," which, I take it, is fever, and at times the temperature is raised. The pain is invariably unilateral, as is the pain in shingles. Any continued pain in both sciatic regions would not be called sciatica by a general practitioner, but would promptly raise the suspicion that something serious was responsible.

I have never known a patient die from what I recognize as sciatica, and whether there is anything known of the pathological condition I do not know. I doubt if there is any pathological evidence. I certainly think that there is some ground for believing that possibly a virus, such as causes a common cold, may at times attack some element in the lower cord, as happens in shingles in various parts of the body. Certainly none of the theories so far explains the invariable one-sidedness of the condition or the invariable complete recovery. In fact one may say that if recovery does not happen in a week or two the condition is not "sciatica," but one of the various conditions so far mentioned by your correspondents.—I am, etc.,

Crewe.

W. L. ENGLISH.

### More Light on the B. Complex

SIR,—The following remarks are prompted by the annotation on this subject in the *Journal* of Jan. 15 (p. 85).

In a series of communications during the last 20 years (for references vide McGowan, 1942) I describe a condition in young pigs—"iron deficiency"—caused by a relative deficiency of iron in the mother sow's milk. It appears in suckling pigs during the first 3 or 4 weeks of life, and is characterized by white diarrhoea, pallor of skin, adiposity, and anaemia, with fatty change in and subsequent disappearance of the cells of the central areas of the liver lobules. The condition is preventable, and curable in its early stages, by the administration of iron. If, however, it is allowed to run its course unchecked, one of the major sequelae which develop in certain cases is another type of anaemia, due to the progressive destruction of the liver lobules from the centre outwards. This anaemia is unaffected by treatment with iron, but responds in dramatic fashion to the administration of liver or liver extract. The symptoms comprise pallor—sometimes there is jaundice—anorexia, vomiting, cyanosis, dyspnoea or "thumps," and often sudden death. There is some emaciation without, however, lack of skeletal growth.

Chick *et al.* (1938), on finding that a condition in the pig resembling that just described was curable by the administration of nicotinic acid, alleged that it was pellagra. I pointed out, however (1938, 1939), that the onus of showing that it was not simply this "iron deficiency" sequela rested on them. The same obligation would seem to be binding on Wintrobe *et al.* (1942) in their study of thiamine deficiency in swine. The symptoms as described are those of the "iron deficiency" sequela—"anaemia of moderate or even severe degree was observed in several pigs" (p. 148); as estimated on only one occasion, and this at the time of death, the red blood cell count in 17 pigs was (with one exception in each of the 4 groups) definitely, sometimes markedly, below normal. Haemoglobin was not determined in any of the cases at any stage. The statement, apparently based on naked-eye observation, that "no chronic passive congestion of the liver was found" (p. 156), while an incorrect description of the pathology of the liver changes to be looked for in "iron deficiency," does not exclude the possibility that changes, past or present, of the liver parenchyma might have been observed if a microscopical examination had been made. Moreover—and this is very important—the pigs were weaned and fed on a highly unnatural diet at

3 weeks of age—that is to say, very early in life at a time when milk should still constitute the major portion of their diet, and, further, at a very critical stage of their existence, when, if this "iron deficiency," possibly well established during the previous 3 weeks, were to be prevented from further development, a diet of natural foodstuffs and one containing a large amount of iron was an absolute necessity. The statement by Wintrobe *et al.* (1940) that the pigs frequently had diarrhoea during the first few weeks of weaning supports, if indeed it does not prove, this thesis.

Such cases are examples, additional to those provided elsewhere (1939a); illustrative of the fallacy of concluding that because a substance cures or ameliorates a condition the previous absence of the substance (from the diet) must have brought it about. They also emphasize the importance of ensuring that experimental animals are quite healthy before being subjected to experiment. I cite (1941) a case in which rabbits, suffering from acute intestinal coccidiosis, were employed in observations from the results of which it was alleged that the addition of calcium to a ration of barley and bran conferred on the rabbits receiving it protection from the effects of an intravenous injection of human tubercle bacilli. I also refer (1933, 1940) to instances where the possibility could not be excluded that pigs and puppies, regarded as normal and healthy and employed for experiments on rickets, were suffering from latent rickets already before being subjected to experiment.—I am, etc.,

Aberdeen.

### Treatment of Chronic Nephritis by Serum Transfusion

SIR,—The importance of serum transfusions in shock and haemorrhage has been well established. In chronic nephritis—or "nephrosis," a word I prefer to indicate this pathological condition—we have to deal with a leak of protein through the damaged kidney. In these cases we restrict the protein intake, but forget that protein can still be obtained from and at the expense of the body cells; in this way we increase the oedema.

Clearly, therefore, the method of treatment for this apparently hopeless condition is to give repeated transfusions of human or bovine serum intravenously or, in children, into the bone marrow of the tibia. I would like to stress the last point, as so often futile attempts are made to find a suitable vein in infants.—I am, etc.,

Southport.

JOHN H. HANNAN.

\*\* In the *Journal* of April 25, 1942, we published a paper by H. Brown, C. H. Gray, and P. L. Mollison entitled "Treatment of the Nephrotic Syndrome with Serum Transfusions." The authors concluded that "in the nephrotic stage of glomerulonephritis a transfusion of concentrated serum is as likely to be followed by an adverse as by a favourable effect."—Ed., *B.M.J.*

### Malaria in British Troops in West Africa

SIR,—I read the article on this subject by Capt. S. B. Hugl and Lieut.-Col. R. R. Bomford (Jan. 15, p. 69) with great interest and appreciation, and feel that they have done service in emphasizing the importance of recognizing the mild clinical types of the disease.

From experience on a smaller scale in another part of "the Coast," I feel the correct emphasis in teaching should be the protean milder manifestations of the disease. How well I remember a number of cases originally treated, while relatively afebrile and in the absence of positive blood findings, bronchitis or rheumatism, but which were later diagnosed subtertian malaria! A common experience was to find the malarial symptoms masked by exacerbation of chronic disease such as tonsillitis. While no experienced practitioner in the Tropics would overlook malaria in such a case, it is possible

that many potentially dangerous attacks of subtertian malaria masked in this way may go untreated in Service personnel returned to the United Kingdom. If no malaria parasites can be found in the blood films, an unusually high B.S.R. with increased monocyte count is often a guide.

With regard to the various clinical types not repeating themselves in the same individual, I can recall one patient each of whose three attacks took the form of very severe gastro-enteritis, but he may have been an exception. But it was noticeable that a series of cases occurring within a few days would conform to the same clinical pattern. This is possibly due to infection by the same mosquito, and consequently the same strain of parasite.

"Malaria-conscious" officers and N.C.O.s make prevention much more efficient, but strict disciplinary measures appear to be necessary, even now, to enforce the wearing of antimosquito clothing by all.—I am, etc.,

J. SANDILANDS, \*  
Temp Surg Lieut-Comdr, R.N.A.R.

### Population Problems of India

SIR.—The recommendations of the Hot Springs Conference are important, because they are the only concrete plans for real improvement of the standard of living throughout the world that have been proposed up to now. The difficulties involved therefore deserve careful consideration. I do not think that your correspondents have answered Prof. Blacklock's article. The food supply of India cannot be considered solely in terms of calories. The standard of diet proposed by the Hot Springs Conference involves a change from a diet that is largely cereal to one in which some 70% of the calories are derived from other foodstuffs. An acre of land producing these foodstuffs yields far fewer calories than when it produces cereals. That is why the diet at present is so largely cereal. It is true that a change to mixed farming, irrigation, the use of fertilizers, etc., would increase the fertility of the soil. It is not possible to work out exactly the possible yields in terms of calories or any other nutrient. But undoubtedly India could not supply a population much larger than at present with a satisfactory diet.

Comparison with Britain is invalid. Britain is, so to speak, an industrial town dependent on agricultural areas abroad. It is not possible for every country in the world to produce only two-thirds (or, as now, one-third) of its food. And even in Britain more of the foods that give a low yield per acre are needed in order to bring the average consumption to a satisfactory level.

The danger is that with an improvement in the standard of living and consequent fall in the death rate the food supply will never catch up with the population. This problem may not be insoluble, but it does exist; the people of India must find their solution. This is only one of the difficulties which are raised by the proposals of the Hot Springs Conference; another is the conflict between the demand for national sovereignty and the need to co-ordinate purchasing power and food production throughout the world.

I hope that no one will infer that I am anything but enthusiastically in favour of the Hot Springs programme; or that I regard famine and war as "Nature's pruning hook"; or that I want to maintain our standard of food at the expense of other peoples; or that I wish to dictate the reproductive habits of the people of India. But we have had one lesson in the consequences of promises made without thought of the difficulties involved in their fulfilment; I do not want to see another.—I am, etc.,

JOHN MARRACK.

The London Hospital, E.1

SIR.—It is to be hoped that Prof. Blacklock's soberly objective article on the population problem of India will not be allowed to become buried under a storm of abuse actuated by political or religious motives.

Experts differ as to the potential wealth of India, but even if the most optimistic estimate be accepted, the development of these potential resources must surely precede the increase in population they are expected to support. Since the reverse has been allowed to happen (present birth rate 34, death rate 22 per 1,000) it is not surprising that famine conditions are endemic in the country. The whole process is a pitifully waste-

ful one. It would seem not unreasonable to suggest that each medical centre (aimed at reducing the death rate) should include a birth control clinic, though admittedly their chances of success in either direction cannot be spectacular while the population remains largely illiterate (73% in 1941).—I am, etc.,

Leatherhead.

M. GRACE EGGLETON.

### Teaching of Anaesthetics

SIR.—While I am in agreement with many of the points raised by Dr. Lloyd-Williams (Dec. 25, p. 827) and Dr. Philip Ayre (Jan. 22, p. 127) as to the future teaching of anaesthesia, I would go further and suggest that practical instruction (as distinct from theoretical) for major operations should be abandoned altogether. A surgical dresser is taught how to deal with an acute abdomen, but is not expected immediately after qualification to operate on such a case, whereas it is more than possible that he will be asked to anaesthetize one. The essential point to my mind is whether the practice of anaesthesia is to be regarded as a specialty or not. If it is, it should be treated in the same way as all other specialized branches of medicine, and be confined to practitioners with special qualifications. Until the medical profession as a whole regards it in this light the present unsatisfactory position will continue. Surgeons themselves are partially responsible for the present anomalous state of affairs by permitting general practitioners to anaesthetize their own cases.

It may be said that there are not enough specialist anaesthetists to go round, but if a sharp distinction were made between anaesthetics for major and for minor operations, and only specialists allowed to handle the former, the minor cases could probably be safely dealt with by the newly qualified house officer and the general practitioner. If students could only be persuaded to forgo the glamour of the operating theatre and to attend dental out-patients and the casualty department, they would obtain a much sounder knowledge of the elements of anaesthesia. This should be supplemented by an adequate course of lectures, while the practical teaching of anaesthesia for major surgery should be entirely postgraduate.—I am, etc.,

London, W.1

MASSEY DAWKINS

### The Record in Urinary Calculi

SIR.—Mr. J. Armstrong's 58 urinary calculi make a very pretty picture, but I am afraid it is very far from being a record. In a paper published in 1934 (*Lancet*, July 28, p. 193) on "Stone in the Lower Urinary Tract in India" I gave details of a case in which I removed 635 stones from the bladder of a very ancient Hindu. The following is a cutting from a reprint of the article.

"Case 1.—This must be, I think, something of a record. An old man was admitted with some pain on micturition and slight pain in the lower abdomen. Palpation revealed a mass in the subumbilical region, tender on pressure. A sound could only be passed into the bladder with difficulty. Radioscopy showed a hazy, ill-defined shadow. On opening the bladder it was found to be absolutely full of small stones, the largest not being bigger than a small nut, and the greater number being the size of a small pea or less. The opening in the bladder was enlarged and the stones removed by the aid of a spoon. There were found to be 635 stones of all sizes. The bladder was entirely filled with them, and there could have been very little room for urine. How many years the old man had taken to accumulate such a vast quantity can only be left to the imagination. The bladder was closed in the usual way, and recovery was uneventful."

Whether this number constitutes a record I do not know, but it must be very near it. It is the equivalent of laying down a fresh stone every month for 53 years. Incredible as this may seem, it is even more astonishing that a man could exist for so many years in the discomfort which such a condition must have entailed without seeking advice. India is, however, full of such surprises. At the other end of the age incidence of urinary calculi, the youngest child from whom I removed a bladder stone was aged 6 months, the stone being the size of a hazel nut. This again is far from being a record, stones having been removed from babies as young as 3 weeks. The obvious inference is that they are sometimes laid down *in utero*.—I am, etc.,

Croydon.

RUFUS C. THOMAS.

### Treatment of Infective Hepatitis with Glucose, Insulin, and Ascorbic Acid

SIR.—One of the chief problems in dealing with cases of infective hepatitis in the Services is the time spent in hospital by patients suffering from this disease. So it was noted with great interest that MacDonald (Aug. 28, p. 261) claimed to have hastened recovery in cases treated by him with glucose, insulin, and ascorbic acid. In view of this it was considered justifiable to try a course of treatment consisting of 10 units of insulin twice a day, 25 mg. of vitamin C three times a day, and at least 5 oz. of glucose spread over the whole day. Ten patients were given this treatment and ten were treated as controls, all receiving a fat-free diet and sodium sulphate.

The duration of symptoms before admission was noted in each case, and the treatment was continued till the urine was free from bile; the total duration of the disease was calculated from the beginning of the first period to the end of the second. The total duration in those cases treated with insulin, vitamin C, and glucose was 10, 9, 10, 10, 13, 9, 9, 11, 17, and 14 days respectively, with an average of 11.2 days. The total duration in the other cases was 12, 11, 12, 18, 15, 18, 17, 7, 8, and 13 respectively, with an average of 13.1 days.

There is obviously no significant shortening of the duration of the disease by the insulin and vitamin C method of treatment, although the number of cases treated is small. It does not seem justifiable to use a treatment such as this unless its effects were profound, owing to the difficulty of obtaining insulin. On the other hand, it was noticed in cases so treated that they definitely improved subjectively at an earlier date than the controls, and suffered less from anorexia and nausea. This suggests that this treatment might be confined to those few cases in which the symptoms, especially vomiting, become severe and indicate a spread of liver damage. Differential blood counts were done on all these cases and showed without exception a relative increase in the lymphocytes.—I am, etc.,

N. S. GORDON,  
Fl. Licul., R.A.F.V.R.

### School Medical Service

SIR.—In reply to Dr. Turner's letter (Jan. 29, p. 161), he will find that the section to which he refers—Section 122 of the Children's Act, 1908—was repealed in the Seventh Schedule to the Education Act, 1921, and its provisions were incorporated in the latter Act. This Act, in turn, will be repealed when the new one comes into force.

I would also like to draw the attention of medical officers to Clauses 31 and 32 of the Education Bill, where the words "serious" and "nature and extent" appear. From this it would seem that it is the intention that no children in the future shall be admitted to special schools unless the medical officers consider that their conditions are serious, and that medical officers making any such recommendations must be prepared to supply the parents and the education committee with certificates stating the nature and extent of the defects. Children requiring special-school education may be suffering from defects of the eyes, ears, lungs, or heart, or orthopaedic or mental conditions. Since doctors making recommendations for children's attendance at special schools may be called upon to give certificates stating the nature and extent of the defects, they would have to possess specialist knowledge in all branches of medicine and surgery in order to do so. As these certificates have only to be given when required, presumably they will only be asked for when objection is taken to the recommendations.

To demonstrate the awkward situation in which a doctor would be placed through it being made his duty to state in his certificate the nature of the defect, the imaginary example may be taken of a councillor's child suffering from seriously defective vision as a result of interstitial keratitis. The doctor would be forced to state in the certificate to be given to the parents and to the members of the education committee that the child's seriously defective vision was the result of congenital syphilis. In cases of paralysis it would be the doctor's legal obligation to give the extent of the paralysis by specifying the names of the particular muscles involved. If the words "nature and extent" are retained, too heavy a responsibility will be placed on school medical officers, and will result in

large numbers of suitable cases not being recommended for special schools because the doctors consider it undesirable to disclose the nature, or feel that they have not the requisite specialized knowledge to state the extent, of the defect.

The open-air schools have in the past perhaps done as much valuable work as any of the special schools. As, however, the cases admitted to these schools cannot be classified as serious, it is presumed that under the new Act the intention is to abolish such schools.—I am, etc.,

Liverpool.

R. GAMLIN.

\* \* \* We have received several other letters pointing out that Section 122 of the Children's Act, 1908, was repealed in the Education Act, 1921.—ED., *B.M.J.*

### Shock Therapy

SIR.—I should be grateful if you would allow me to reply to the letters that have followed mine of Dec. 25. Most of these letters have been from psychiatrists, and this has disappointed me, since my aim was to sound the opinion of the profession as a whole. The general practitioner is probably too busy at present even to read letters, and yet I think his opinion on specialist practice should constantly be sought by specialists, if for no other reason than that the G.P. himself lives among his patients, among the therapeutic failures as well as among the successes.

I am well aware that a certain number of psychiatrists who are students of human nature are using various kinds of shock therapy as an adjunct to their psychotherapeutic work. These have nothing to fear from a letter from me to the medical press. They will continue their work, retaining, modifying, and discarding according to their careful observation of effects. Quite different from this is the idea which is developing that the treatment of mental disorder is shock treatment of one kind or another, and that this is something which can be ordered and given like chemotherapy in the case of septicaemia. No treatment of mental disorder will ever be invented which can be properly practised by anyone but a student of human nature. My letter has had some value in that it has produced an authoritative statement that shock therapy (of whatever kind) is not a treatment in itself. The opinion which I expressed—that shock therapy of mental disorder (even if it can be valuable in good hands) is a serious setback to the health of psychiatry—is strictly a personal one, and it is only fair to my psycho-analytic colleagues for me to make it clear that my letter expressed only my personal feeling.

Several of those whose letters were published assumed that I had psycho-analysis in my mind as an alternative to shock therapy. As a matter of fact I did not mention the word, though it is true that my training has been in the psycho-analytic discipline. The alternative which I am advocating is good general management, good personal doctoring and nursing, with toleration of therapeutic failure. This is extremely difficult to put into practice in the case of hopeless psychiatric material; but for every hopeless case there are hundreds, or rather thousands, of hopeful cases, and it is for them that we must plan psychiatric practice. This may sound surprising to some institution psychiatrists, but general practitioners will understand what I mean when I say this—that when medical science is able to control the physical part of certain common conditions, such as influenza, rheumatism, and high blood pressure, a great deal of serious depression, paranoia, and chronic hypomania will be revealed. This will have to be treated as "flu and rheumatism and high blood pressure have always been treated—by personal doctoring and nursing. One of the really useful things the psychiatrists used to teach us was that depression phases tend to pass spontaneously with no more than an intelligent toleration of the condition on the part of those caring for the patient, watch being kept for suicidal attempts, deliberate or accidental. Freud made this teaching understandable by pointing out the relation of melancholia to normal mourning, which has its term and from which recovery can be expected. If the psychiatrists are really concerned to give help they can do so very much more than (with notable exceptions) they do now about occupation therapy. Perhaps the term "occupation therapy" is unfortunate, because it reminds one of the proverb about "idle hands," whereas a better term would indicate that what is wanted is a specialized form of

vocational guidance which gives subjective reality its proper place alongside the patient's relation to the external world.

One might have been content to let research into the value of shock therapy take its own course if it had not been for a certain communication which I received with regard to post-war planning. I was told that when peace comes an institution will be set aside for psychiatric illness in childhood, in which psychotic children will be treated by shock therapy. Just like that. Now my friend Dr. Rogerson may be gravely in error in thinking that psychosis in childhood is rare. In my opinion it is common. What schizophrenia and depression and paranoia and hypomania look like in childhood is a matter outside the scope of this letter, but the point is that the vast majority of cases recover spontaneously with right management, or, at any rate, manage to find some way of life which suits the type of personality. Those who use shock therapy in the treatment of adults generously admit that they have no idea how it works when it does work. I hoped by mobilizing general medical opinion to make it impossible in England for this research to be done on children.—I am, etc.,

London, W 1

D. W. WINNICOTT.

SIR.—There is nothing to be ashamed of in empirical medicine. But with the enormous strides in the scientific field it is inevitable that the sincere clinician must wish to know *how* he has attained results in his patients; it is not sufficient just to cure them. In other words, he must have some scientific framework of pathology or psychopathology within which to fit his clinical facts, and seek to explain any cure or attempt at cure with the language of his theory.

But let us remember that our psychopathology arose out of carefully observed clinical facts. In effect the critics of electric convulsant therapy are upset because they seek to cure with "love," and the exponents of E.C.T. are alleviating certain types of mental disorder with what appears to be "hate" methods. Each side is using the opposite antinomy of the original love-hate dualism. But do not Freudians get their results in depth analyses through the expression of the instinctual hate-impulses during the real negative (projection) transference phase?

Most of us can recollect some antisocial individual who has changed his ways without treatment of any specific kind through the effect on himself of another's example, so *shocking* that it had the effect of making him afraid of becoming likewise, and so hating his own way of life. If we don't like getting good or bad results without knowing sufficiently how these came about we shall, of course, criticize the same thing in others. The real danger we fear is (apart from inflicting actual physical lesions) lest any method becomes a "magic" to be used haphazard and carelessly in unsuitable cases.—I am, etc.,

London, N.W. 5.

J. C. MACKWOOD.

SIR.—Dr. Winnicott's letter on convulsion therapy has started a red herring which, so to speak, is careering across the psychiatric terrain with the hounds in full pursuit. Accordingly a good deal of speculative and irrelevant comment has been evoked to befog the issue.

Admittedly the treatment is purely empirical, has no rationale, and was based originally upon a misconception. It will consequently tend to disconcert and repel the scientifically trained mind. But clearly, as against this, first importance must be given to the fact that it works—it is often brilliantly effective—in a considerable proportion of cases. Does Dr. Winnicott seriously contend that in spite of successful results a treatment should be discarded if we do not know how it acts? This all-important question of results receives no mention in his letter. It is the theoretical aspect entirely that alarms him. The treatment, he thinks, is too violent (experience shows that it is not); the patient probably consents from an impulse akin to a suicidal one (this is not uncommon in other forms of treatment as well); it gives scope to the doctor's unconscious antagonism (does this not happen in psychotherapy too?); it offers a by-pass to true understanding of human nature (understanding is not enough without the power to alleviate). To bring in psychotherapy as the alternative is obviously irrelevant, as it is well known that the cases responding best to electrical convulsion treatment are as a rule unsuited for and inaccessible to analytical forms of psychotherapy.

In the evolution of medicine there is bound to be a place for the random discovery. After over 5 years' extensive trial of convulsion therapy one is surely compelled to emphasize how it has justified itself in the amount of suffering it has relieved, already very great. The attempt by theoretical objections to throw discredit upon a valuable form of treatment is likely only to result in discrediting those who make use of them. Their critical attitude is strangely reminiscent of the early opposition to psycho-analysis.—I am, etc.,

London, W 1.

FREDERICK DILLON.

### The Prisoner-of-War Mentality

SIR.—Nobody could regret more than I that my communication of Jan. 15 last should be depressing; we should thank Col. L. W. Harrison for trying to lighten the gloom. But in support of my previous statements I should like to refer him to Mr. Eden's comprehensive review on the matter in the House of Commons on Jan. 28. Commenting on communications received in this country from prisoners in Japanese hands, which universally suggest that the writers are being well cared for and are in good health, he says: "There is no doubt from what we know about particular areas that some of these communications at any rate are in terms dictated by the Japanese authorities"; and "... the true state of affairs is a very different one so far as the great majority of the prisoners in Japanese hands is concerned."

The point I wished to emphasize was that while we are indebted to Major P. H. Newman for correlating some material facts with psychological theory, we now have very many more, and awful, material facts on which we should have to base any future psychological treatment.

I am convinced that the Western mind has yet to grasp the Japanese mentality and its baneful influence. I would even go further and say that nothing, so far as I am aware, is being done officially or otherwise to enlighten our ignorance on the subject.—I am, etc.,

Peter Wood.

B. RICHARDSON BILLINGS.

### The Mosley Incident

SIR.—I do not intend to express an opinion one way or the other on the Mosley incident. But Sir Farquhar Buzzard's letter raises a most important point. He utters a protest—albeit rather a belated one—at the loss of professional secrecy which every patient should be able to claim as a right. I am afraid Sir Farquhar is a trifle behind the times. The average citizen has no such right to-day.

The bare expression of a medical attendant's opinion without a detailed statement as to what disease the patient is suffering from would not be sufficient to claim him exemption from fire watching, Civil Defence volunteer duty, or his wife exemption from forced service in a factory. On the contrary, the medical attendant has to allude to the disease—details of which must be submitted, and are scrutinized and even criticized by lay officials at Labour Exchanges. Suppose an unmarried mother were to make a statement to me as to her pregnancy, the bald statement "In my opinion her life would be endangered (or her health endangered) by her work in a factory or other form of National Service" would not be accepted by a National Service officer. On the contrary, such officials are encouraged by the Ministry of Labour to make searching inquiries into the actual disease or condition and its consequences. Further, they are even supplied with a glossary of medical terms to help them in their investigations. They frequently discuss the patient's health before a committee (composed of lay persons, and, in one instance known to me, such persons were neighbours of the unfortunate patient).

I once referred a patient back to the Labour Exchange because by virtue of brachial neuritis she was unable to work in a first-aid post. She was referred to a lay committee of the Labour Exchange, all of whom discussed her case openly, and one even went so far as to suggest that her past treatment had been useless! Another patient referred by a doctor for exemption on account of a major operation (hysterectomy) was told by a Labour Exchange official: "That oughtn't to take more than three weeks!" I may ask how much professional secrecy existed here.

I could supply many more instances, but perhaps the best of all is the following. A married woman who was pregnant brought in a certificate for exemption. Being nervous, she murmured the contents in a low voice, and was greeted by the woman official with these words: "Come on, now! Speak up! What is your condition?" Adding in a voice of thunder: "You're pregnant, aren't you?" The entire room could hear this effort. I trust Sir Farquhar would have voiced his indignation as I did. Certainly it would be in a worthier cause than that of Sir Oswald Mosley!—I am, etc.,

Ilford, Essex.

ROGER M. NOORDIN.

SIR,—Sir Farquhar Buzzard must not be allowed to get away with that pontifical letter unchallenged. The *B.M.J.* is not a professorial chair. "The 'patient' in this case is a private citizen with a private citizen's rights, including that of entertaining his own political faith." What, even if it is the faith of the Germans; even if it delights in their bestial means—rubber bludgeonings, calculated brutality, inducement by fear; even if it seeks to stir up racial hates? Nonsense. The next sentence: "This country is at war with nations who contest that right and who do all in their power to suppress it, and it is largely to maintain what we believe to be an individual freedom of faith that we are fighting." Are we fighting to allow people to adopt the cruel and obtruding doctrine of Fascism? Nonsense, again. The herd was quite right in being sensitive to the release of the head of an organization whose associates are costing us an ocean of sweat, blood, and tears. The herd was obeying a sound instinct and arrived at sounder conclusions than those to which a restricted and juridical view—the typical professorial psychology—has brought Sir Farquhar. Can anyone doubt what part the "patient" would be playing if England were as Norway is? Sir Farquhar does not mention the wealth of the "patient," which had something to do with rousing the herd's suspicions. About the illness itself I am mystified. Is His Majesty's Prison Service unable adequately to look after a case of thrombosis? As for Sir Farquhar's suggested report—"In our opinion the health and perhaps the life of Sir Oswald Mosley will be endangered by his further detention"—that might truthfully refer to a cold or a corn.—I am, etc.,

Beckley, Sussex.

C. G. LEAROYD.

SIR,—In your issue of Jan. 29 I observed a letter from Sir Farquhar Buzzard. It is surprising, this criticism by so eminent a member of the profession. He refers to that section of the public who protested against the release of Mosley as "illogical, indefensible," and he further refers to the "hysterical Press and ignorant and foolish questions in the House of Commons"—a rather sweeping condemnation of these great institutions. This attitude throws a doubt on his own logic. No one would question the right to medical advice in a case of this kind, but this arrogant renegade, owing to his wealth, is able to obtain the services of very eminent members of the profession to press his claims for release. Public opinion—could also refer to the non-vocal section—was very much on the side of the "hysterical Press and ignorant House of Commons," and this reviving of an unpleasant episode would have been better left alone.—I am, etc.,

Southborne-on-Sea.

E. A. CHARTRES.

SIR,—Sir Farquhar Buzzard agrees that owing to the war "it became necessary to prevent the patient [Sir Oswald Mosley] from actively spreading his gospel." It is precisely anxiety on this point that led large and responsible sections of the public to protest against the release, at a critical phase of the war, of Britain's former Fascist leader and his wife. They were anxious lest this action would encourage and even facilitate the spread of propaganda detrimental to unity within the nation and between us and our Allies, and lest it would weaken the national effort and the morale of the troops. Their protests certainly did not reflect, as Sir Farquhar suggests, the desire for Mosley's personal suffering or even his death. It should be recalled that those who protested included the principal trade unions, deeply involved in the war effort. Yet they are dubbed by Sir Farquhar as confused, actuated by "herd psychology," acting illogically and indefensibly, and as displaying lamentable ignorance; while the Press is accused

of publishing uninformed and hysterical criticism, and M.P.s of asking ignorant and foolish questions. Such a diatribe against the British public for democratically expressing their opinion in the ways open to them on a matter which they believed affected their country's security seems inconsistent with Sir Farquhar's plea for tolerance of individual freedom of faith. Indeed, he has misunderstood the spontaneous and widespread hostile reaction to Mosley's release. It is, surely, a healthy sign that ordinary men and women are so much awake to the dangers of the doctrine which led to Mosley's detention, for it is the very embodiment of this doctrine of Fascism which we are aiming to destroy utterly abroad.—I am, etc.,

London, N.W.1.

P. D'ARCY HART.

### Plastics in Splint-making

SIR,—I read with interest Mr. James P. Campbell's note in the *Journal* of Jan. 29, and should like to comment on some of his statements.

Mr. Campbell says the manufacture of such a splint is in an experimental stage, presumably because he has only recently started to use them. I have made splints and other appliances in "perspex" for at least six years, and discovering very few surgeons who knew about the possibilities of this material I wrote a short introductory article on the plastic splint (*Lancet*, June 26, 1943, p. 803). These splints have been satisfactory for many purposes, and I can assure Mr. Campbell that not only is "perspex" non-irritant to the skin but is tolerated by any tissue. We all know "nylon" and "portex," used in sutures and dentures respectively; "perspex" has the same property of lying inert in the tissues, permitting its use as bone plates and in arthroplasties.

Mr. Campbell has also underestimated the strength of "perspex" in using 3/16-in. sheet! He will find 1/16-in. sheet adequate, with the great advantage that it can be cut with ordinary scissors after preliminary local heating over a small flame. His splint for a wrist will then weigh 3 oz. instead of 9 oz., and be infinitely easier to shape into greater accuracy. Another point which might be mentioned is the property of non-absorption. This is a valuable quality in some circumstances, but where the splint is complete and not just a slab, condensation of moisture is troublesome. The splint will then require holes drilled at intervals or a lining of thin felt.

Lately many people have written to me saying they have had difficulty in moulding splints where there are double curvatures. I hope there will soon be on the market suitable splints preformed as regards the main curves, and requiring only local moulding and fitting, thus ensuring a well-fitting splint of even thickness. Another aid to such work is a softener, which allows the treated "perspex" to be moulded in a plastic state, hardening twelve hours later; no heat is required. Leather retaining straps rather detract from the unique appearance of these splints, and I suggest that they should be replaced by transparent flexible plastic strips. Mr. Campbell says cracks cannot be repaired by heat. He will find that any cracked pieces can be "welded" by allowing glacial acetic acid to run in by capillary attraction. The acid dissolves the "perspex," allowing the edges to join together.—I am, etc.,

A. MACGOWAN.

### Photomicrography with Ordinary Cameras

SIR,—I am glad that Dr. Silcock (Jan. 29, p. 164) has added his testimony to the value of the method of photomicrography I described, and I must also congratulate him on being apparently the first to publish any account of the method, for during an avid reading of photographic and microscopical literature during thirty years I have never seen it described, and the textbooks know nothing of it. I may perhaps say that an earlier paper of mine describing the method specially for Leica users would have appeared in *Leica News*, but the war prevented publication, and a similar fate befell a more general account in 1942. Now that attention has been drawn to the method I trust that it will be widely adopted. Its value in industry is obvious.

It is important to realize that the method is applicable to all types of optical apparatus, and that for photomicrography at least it is not just a makeshift but scientifically the most correct way of taking a photograph. If the camera used had

a 10-in. lens it would give photographs identical with that seen by the human eye, and at least as good as those taken by the most elaborate photomicrographical apparatus. It would indeed make the latter as obsolete as the huge contraptions with which the pioneers of ordinary photography did their excellent work.

It is also necessary to emphasize that the simple method described by Dr. Silcock will not give good results unless the viewing eye is emmetropic. If this is not so, either a camera with focusing screen must be used or, much simpler, a gadget like I described if the correct focus is to be obtained. Actually this is not so critical as one might anticipate, as the microscope never works at a greater aperture than F. 22, and probably for this reason I find that photomicrographs taken with a 2-in. lens show appreciably greater depth of focus than my eye has.—I am, etc.,

Winstford,

W. N. LEAK.

## Obituary

JOHN S. FAIRBAIRN, F.R.C.P., F.R.C.S., F.R.C.O.G.

Dr. John S. Fairbairn, who died on Jan. 22, lived his professional life in London but never lost touch with Scotland, and went to live there when he retired from practice eight years ago.

John Shields Fairbairn was born on Dec. 21, 1865, at Bathgate, West Lothian, the elder son of Andrew Martin Fairbairn, D.D., first Principal of Mansfield College, Oxford. From Bradford Grammar School he entered Magdalen College, Oxford, with an open science demyship, and in 1891 gained first-class honours in the School of Natural Science; he went to St. Thomas's Hospital for his clinical course, and graduated B.M., B.Ch. in 1897, after taking the English Conjoint Diplomas. He obtained the F.R.C.S.Eng. in 1900, and in 1909 was elected F.R.C.P.Lond. Dedicating himself early to the practice of gynaecology and obstetrics Fairbairn became in turn pathologist to the Chelsea Hospital for Women, physician to the General Lying-in Hospital, York Road, and obstetric physician and lecturer in midwifery and diseases of women at St. Thomas's. At the Royal College of Physicians he served as examiner for four years, councillor for two years, and Bradshaw Lecturer in 1934, when his subject was the medical and psychological aspects of gynaecology; he also examined for the Universities of Oxford, Cambridge, Glasgow, London, Birmingham, and Leeds, and for the Society of Apothecaries of London. During the last war he served on the *à la suite* staff of the 5th London General Hospital with the rank of captain, R.A.M.C.(T.). He was one of the Foundation Fellows of the Royal College of Obstetricians and Gynaecologists in 1929 (and afterwards held office as President), and in the same year was elected Honorary Master of Midwifery by the Society of Apothecaries; the Obstetrical Society of Edinburgh made him an Honorary Fellow.

Fairbairn joined the B.M.A. in 1903, was secretary of the Section of Obstetrics and Gynaecology in the following year, and twice held office as president of that Section—in 1924 at Bradford and in 1935 at Melbourne, whose university gave him the honorary degree of M.D. on that occasion. He had been a frequent contributor to this and other medical journals; he edited for some time the *Journal of Obstetrics and Gynaecology of the British Empire*, and was the author of *Gynaecology with Obstetrics* and of a *Textbook for Midwives*; he was also editor of the *Practitioner's Encyclopaedia of Midwifery and Diseases of Women*. He preceded Sir Comyns Berkeley as chairman of the Central Midwives Board for England and Wales. In March, 1936, just before they left London, Dr. and Mrs. Fairbairn were entertained to dinner in the Langham Hotel, and over 100 guests were present under the chairmanship of Sir Ewen Maclean, who eulogized Fairbairn's work in furtherance of the teaching and practice of midwifery throughout Britain. At Lossiemouth, where he had spent many summer holidays, he was able in retirement to indulge his hobbies of golf and gardening.

We are indebted to Dr. J. P. HEDLEY for the following appreciation:

The death of John Fairbairn at Lossiemouth came as a great shock to his many friends, and perhaps especially so because few of us had been able to see him on account of the war

during the last four years. In peacetime he came to London for several weeks each year to see his friends and enjoy moving about in the old surroundings in which he was always so happy.

He came up to St. Thomas's in 1893 from Oxford, where he had taken a first class in the honours school of Natural Science; after qualifying at Oxford he was house-physician and obstetric house-physician before becoming obstetric tutor and registrar in 1898. Four years later he was appointed to the staff of St. Thomas's as assistant obstetric physician. His father, the Rev. Dr. A. M. Fairbairn, the first Principal of Mansfield College, Oxford, was a distinguished scholar, and it may have been from him that he inherited his devotion to education. Fairbairn was an enthusiastic teacher at the time when I first met him as obstetric tutor; later as a clinical teacher he was quite exceptional. For years generations of St. Thomas's men looked upon him as a great teacher, and very many have reason to be grateful for what he taught them. Fairbairn had original ideas in the organization of a complete obstetric service, and did more than anybody to plan and put into force the modern methods of education needed for such a service. He always made a great point of the indivisibility of obstetrics and gynaecology and accentuated this point in the title of his well-known book *Gynaecology with Obstetrics*. He taught that obstetrics was one of the most important parts of preventive medicine, and in his book he says, "At no stage in his hospital career can the student obtain a clearer object-lesson in the practice of preventive medicine than while studying obstetrics, gynaecology, and paediatrics: together they form a concrete example of the direct application of the teaching, otherwise wholly academic, in hygiene and public health." He always stressed the greater importance of training than of examinations.

At the Society of Apothecaries he was largely responsible for the institution of the Mastership of Midwifery, the first higher diploma in obstetrics in the country, in which all candidates had to have postgraduate experience in obstetrics, paediatrics, and public health, including a resident house appointment in an obstetric unit. Later, when the College of Obstetricians and Gynaecologists was founded—of which Fairbairn was the second President—similar training regulations were made. He was a very active member of the Central Midwives Board, both before and after becoming its chairman. He was just as keen on the education and training of midwives as of doctors. In connexion with the General Lying-in Hospital he conceived and brought into being the Camberwell Post-Certificate School, to which midwives came for refresher courses; this proved a great success, and has been the model for other schools spread over the country.

Although Fairbairn's greatest work was educational, there was no member of the St. Thomas's staff who was more conscientious and thorough in all his hospital duties and the care of his patients. His interest in hospital affairs was not confined to his own department: he was always ready to work for any new development he thought to be good. The loss of him to medicine is great, but fortunately he has left much in his writings that will be a guide and help to many in the future.

A. STEWART WILSON, F.R.C.S.Ed.

We have received news of the death on Nov. 2 at his home in Durban of Dr. A. Stewart Wilson. He had been ill for the last two years.

Alex. Stewart Wilson qualified M.B., Ch.B. at Glasgow in 1911, and took the F.R.C.S.Ed. in 1918. When the Royal College of Obstetricians and Gynaecologists was formed in England he was one of the very few South African doctors whom the College elected to foundation fellowships. After holding resident appointments in the Western Infirmary, Glasgow, he went to South Africa in 1913 and joined the staff of Addington Hospital, with which he was associated throughout his life as resident medical officer, senior visiting gynaecologist, and chairman of the medical staff committee. During the last war he served in France and at the South African Military Hospital, Richmond. Returning to South Africa after the war, Stewart Wilson began practice as a consultant gynaecologist in Durban, and rapidly became the leading member of his specialty in Natal. He was a member of the South African Medical Association (B.M.A.), and was president of the Natal

Coastal Branch and chairman of the Gynaecological Section at one of the annual meetings. He took a keen interest in the Berea Nursing Home, having been chairman of its board of directors and been largely responsible for its expansion and development. He was a brilliant operator, an original thinker, and a man of sound judgment. At the hospital there was keen competition to act as his resident, and many young doctors have expressed appreciation of his skilful teaching and kindly encouragement.

Among his varied interests outside his work were several branches of sport—he was a liberal patron of many of the sporting societies of the town—the British Empire Service League, a number of charitable institutions to which he contributed generously throughout his life, and the welfare of nurses—the training school for midwives was started through his efforts. A loyal and trusted friend, he will be sadly missed by his patients and by friends inside and outside the profession. He is survived by his wife and daughter, by whom he was devotedly nursed during his long illness.

#### THE LATE DR. G. C. ANDERSON

Viscount Dawson of Penn as President of the British Medical Association has received from Sir Alfred Webb-Johnson, President of the Royal College of Surgeons of England, a copy of the following resolution, unanimously adopted by the Council of the College at its last quarterly meeting: "The President and Council of the Royal College of Surgeons of England hereby express their deep regret at the death of Dr. George Cranston Anderson and their sympathy with the British Medical Association in the loss of their Secretary. The Council desire to place on record their admiration for Dr. Anderson's able services to the profession, particularly in regard to recruitment for the Services, and their appreciation of his success in bringing about a closer friendship between the College and the British Medical Association."

A copy has been received from the Royal College of Obstetricians and Gynaecologists of the following resolution passed at its last quarterly meeting: "That the profound sympathy of the President and Council be tendered to the British Medical Association in the great loss sustained by the death of Dr. G. C. Anderson."

Further messages of sympathy on the occasion of the death of Dr. Anderson have been received from the New Zealand Branch (by cable), from the National Temperance League, and from the Surgical Instrument Manufacturers' Association.

The death on active service of Fl. Lieut. C. F. H. WIESSNER was briefly announced in our issue of Jan. 1 (p. 28). Charles Frank Horace Wiessner was born in 1912. He studied medicine at Cambridge and the Middlesex Hospital, qualifying M.R.C.S., L.R.C.P. in 1938, and M.B., B.Ch. in 1940. He was for a short period in general practice in South-East London until appointed to a commission in the Medical Branch of the Royal Air Force Volunteer Reserve on March 21, 1941. At the date of his death he was medical officer at an Air Training school over-seas.

The death has occurred at Grimston, Norfolk, of CHARLES STUART WOODWARK, J.P., aged 66, fourth son of late George Woodward, a prominent citizen of King's Lynn out the turn of last century. Dr. Woodward was a younger brother of the late Lieut.-Col. G. G. Woodward, M.P., and of Sir Stanley Woodward. He was educated at St. Bartholomew's Hospital, whence he qualified in 1902. Some years ago a breakdown in health necessitated his retirement from practice, and lately an even more serious malady developed and caused his death. He was in general practice at Grimston for the whole of his active career, and his high reputation in the neighbourhood was shown by the addition of his name to the Commission of the Peace. A member of the B.M.A., he was chairman of the West Norfolk Division in 1922. He married Miss Winifred Hill, who survives him with their three sons and two daughters, all of whom are in the Services; one son is a squadron leader in the R.A.F., and another is a prisoner of war.

We regret to record the death on Jan. 14 at King's Langley of Dr. ELIZABETH THACKRAY. After qualifying M.B., B.S. in 1903 from the London School of Medicine for Women and the Royal Free Hospital, Dr. Hill (as she then was) held the post of house-surgeon to Sir James Berry at the Royal Free Hospital. She was next appointed assistant medical officer to St. Pancras Infirmary, resigning that position on her marriage to

Dr. Christopher Thackray, the medical superintendent. She resumed medical work during the last war, returning for part of the time to her post at the Infirmary, while later she was a medical examiner of recruits for the W.A.A.C. She retired finally from practice in 1918. Dr. Thackray had great personal charm, which endeared her to all her colleagues.

Dr. FRANCIS WILLIAM JOLLYE died suddenly on Jan. 14 at Alresford, Hants, aged 80. He was a native of Spalding, Lincs and left Cranbrook School in Kent to study medicine at King's College Hospital, winning the Warnford entrance scholarship in 1882 and other scholarships in successive years. He qualified M.R.C.S. and L.S.A. in 1885, took the D.P.H. in 1890, the F.R.C.S.Ed. in 1897, and the M.D. of Durham University in 1903. Settling in practice at Alresford he became M.O.H. under the rural district council, and held other local appointments. Dr. Jollye was a Fellow of the Society of Medical Officers of Health, joined the British Medical Association in 1891, and was president of the Southern Branch in 1913. A number of papers by him on clinical subjects appeared in these columns during the 'nineties. He retired from practice in 1937.

Dr. PURNELL PURNELL, whose death took place on Jan. 22 at Streatham, was the son of J. J. Purnell, F.R.C.S., and was educated at Epsom College and at Guy's Hospital. He qualified M.R.C.S., L.R.C.P. in 1889, and practised for very many years at Streatham. His chief claim to the grateful recollection of his professional colleagues lies in his unwearied efforts on behalf of the Royal Medical Foundation of Epsom College, in recognition of which he was some years ago elected a vice-president. He collected for the Foundation in all not far short of £3,000, a total which has been but once, or possibly twice, exceeded by any individual member of the profession. He married Miss Ivy Florence Goldsmid.

The death occurred at his daughter's house at Gwelo, S. Rhodesia, of THOMAS OVENS SCOTT at the age of 81 years. The eldest son of the head master of the Academy of Berwick-on-Tweed, he took the M.A. of Edinburgh in 1882, and entered the Presbyterian Church. While holding a pastorate at Newcastle-upon-Tyne he studied medicine, and graduated M.B., B.S. at Durham in 1897. After seven years, during which time he was appointed honorary surgeon to the Throat and Ear Hospital, Newcastle-upon-Tyne, he moved to Leeds, where he remained in general practice till 1934. Quiet and unassuming, and unselfish in his true Christian humility and sympathy, yet staunch and unchanging in his faith, Dr. Scott was a tower of strength in time of need. To all his many friends he has left memories, and all of them pleasant—a rich legacy. At the end of a vigorous healthy life he died peacefully in his sleep—a man without envy and without enemies. He leaves a daughter and three sons, two of whom are doctors—one at Sunbury-on-Thames and one in Leeds.

Mr. W. McAdam Eccles writes: May I emphasize two points in memory of the late Dr. C. E. DOUGLAS. One his great keenness on all matters concerning the B.M.A., shown especially during the World Tour of 1935. Dressed as the "Oldest Inhabitant" on the occasion of a fancy dress parade, he was awarded the first prize, but did not show signs of "old age". To signalize permanently the chess-playing during the trip he presented the "Melbourne Chess Cup" to the B.M.A., to be competed for annually and presented at the meeting of the Representative Body to the winner, to be held for twelve months.

The ashes of the late Mr. CECIL ROWNTREE, F.R.C.S., were scattered on Jan. 27 at a brief ceremony, the first of its kind in the history of the hospital, on the spacious lawn in front of the Woolwich Memorial Hospital, Shooters Hill. Those present were Mr. Tom Rowntree, F.R.C.S. (son), Air Commodore E. G. Dixon (chairman of the hospital), Mr. E. T. C. Milligan, F.R.C.S. (chairman of the medical committee), Mr. A. W. Lincoln Bell, F.R.C.S. (resident surgical registrar), and Miss C. E. Lotherington (matron). The chairman of the hospital, in paying tribute to Mr. Rowntree, referred to the affection and respect in which he was held. He had helped to design the hospital and was its first surgeon. He placed his exceptional surgical skill and advice ungrudgingly at the disposal of the public of Woolwich, the board of management, and the medical and nursing staffs. He would ever be remembered as an inspiration to the staff and with gratitude by those who benefited by his surgery. To his wife and family he offered, on behalf of the hospital, deepest sympathy. Mr. Milligan, who performed the ceremony, said that Mr. Rowntree was essentially a happy man, animated by an ardent desire for hospital efficiency through unity between surgeon and surgeon, and between the medical committee and the board of management. In this he showed himself to be a true statesman, for he saw that such unity based on good will was the secret of sound homes, team-work in industry, and a united nation.

## Universities and Colleges

### UNIVERSITY OF CAMBRIDGE

At a Congregation held on Feb. 21 the following degrees were conferred:

M.B., B.CHIR.—D. Ainslie, F. Ashton, V. L. Ballington, A. Carpenter, P. Cook, F. H. Epstein, W. G. Evans, A. H. M. Fisher, W. M. Foreman, A. Hallinan, R. F. Hobson, R. G. F. Parker, T. J. Rendle-Short, L. A. Cook, L. J. Rowley, I. A. Roxburgh, F. A. R. St. John, D. H. K. Soltau, G. Somerville, R. G. Tasker.

1 In person.

### UNIVERSITY OF LONDON

#### WESTMINSTER HOSPITAL MEDICAL SCHOOL

An examination for two entrance scholarships in anatomy and physiology will be held on March 15 and 16. For further particulars application should be made not later than Feb. 21 to the Secretary, Westminster Hospital Medical School, 17, Horseferry Road, S.W.1.

### ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly Comitia of the College held on Jan. 27, with the President, Lord Moran, in the chair, the following were elected Representatives of the College: Dr. B. T. Parsons-Smith on the Council of the Queen's Institute of District Nursing; Dr. A. S. James on the Court of Governors of the University of Birmingham. It was announced that the President was nominating a committee to preside over the work of revision of the College's publication *The Nomenclature of Diseases*. It was also announced that arrangements have been made for examinations for the Membership of the College to be held in Poona and in Cairo during May and June, 1944.

The following candidates, having satisfied the Censors' Board, were elected Members of the College:

C. R. Amies, M.D.Lond., J. Benn, M.B.Leds, Surg. Lieut.-Cmdr. R. N. Mary E. Elliott, M.B.Lond., J. A. Fisher, M.D.Belfast, J. H. Gould, M.B.Lond., E. Gutzmann, M.D.Munich, D. B. Jeffile, M.B.Lond., T. D. Kellack, M.B.Camb., Zena E. Moncrieff, M.B.Aberd., R. T. C. Pratt, M.B.Oxon, C. Preisch, B.M.Lond., J. A. Corfield, J. C. Gorton, G. S. Crockett, J. S. N.V.R., H. W. Salmon, M.B.Lond., H. T. N. Sears, M.B.Lond., Sharkey, M.B.Lond., A. I. Spriggs, B.M.Oxon., A. W. Taylor, M.B.Leds, J. P. M. Tizard, B.M.Oxon., Capt. R.A.M.C. M. D. Young, M.B.Lond.

Licences to practise were granted to the following 133 candidates (including 23 women) who had passed the Final Examinations in Medicine, Surgery, and Midwifery of the Conjoint Board, and have complied with the necessary by-laws:

J. Alterman, C. van C. Anthony, C. G. Ball, G. H. Bancroft-Livingston, R. E. Barnes, J. H. E. Bergin, V. H. Bolton, J. A. P. Bowen, T. J. Brady, Elizabeth T. Brash, L. D. Bromley, H. D. Browne, J. Bullough, K. H. Bywater, A. S. Carnahan, J. A. Clarke, J. R. Clout, H. T. Coles, J. R. C. Cooper, Margaret J. Corbridge, J. A. Corfield, J. C. Gorton, G. S. Crockett, J. S. N.V.R., G. A. N. Davis, Deborah Doniach, Kathleen A. D. Drury, D. R. Duff, Margaret J. Dunn, R. Earl, P. M. Edis, A. W. Edridge, Olga M. Elliot, A. B. A. Evans, M. E. Evans, J. M. Fabricius, Winifred J. Ferraby, V. H. Finlayson, J. R. Forsyth, I. H. Fothergill, S. A. M. Garbhan, B. Haigh, L. H. Hamlyn, R. J. Harrison, G. Handridge, Ruth M. Haslam, V. S. Hawkes, S. F. Hewson, H. F. Hitt, Duke E. Holden, F. L. Holroyd, J. E. G. Hope Scott, R. Humphrey, R. W. L. Hurr, Lois E. Hurter, J. R. Hutchinson, E. Jackson, Rosemary Jackson, C. D. T. James, L. F. Jepson, G. Jones, Jean L. Kahn, D. E. R. Kelsey, J. C. Lawrie, G. de J. Lee, Sheila D. Lee, A. V. Livingston, S. S. London, J. Lorber, P. Lucas, M. B. Mellroy, A. G. Mackenzie, I. M. MacLean, N. L. M. MacLennan, R. Majidani, A. S. Maitland, J. M. Mallet, J. T. Mastroianni, J. K. Morgan, Catherine A. Noll, D. C. J. B. Nixon, A. W. Nurick, A. C. F. Ogilvie, D. H. D. Paine, C. R. Palmer, T. J. S. Patterson, B. W. T. Pender, C. P. Perkins, Dorothy M. Phillips, Mary Pilling, W. E. Prosser, A. A. Quilliam, J. V. Radley, D. H. Rea, D. L. Rees, L. J. Rowley, Helen M. Russell, J. T. Seales, C. L. E. H. Sharp, Edith M. Sharpe, G. N. Shell, J. Shenfield, P. D. W. Shepherd, R. N. Sidebottom, B. C. Smith, Y. G. Sofer, G. Somerville, R. Spielmeier, R. V. Sturton, S. M. Talbot, A. Taylor, H. Taylor, C. G. Tolerson, J. M. Thomas, W. E. W. Tilleke, Margaret R. Todd, L. J. Totham, E. J. S. Townsend, E. L. Tricker, G. Trosser, E. C. Turton, Ambrosio B. Vaughan, B. H. Vawdrey, P. Venables, C. I. Waters, K. Whitmore, Dorothy Willoughby, Joan B. Winstanley, P. W. Woodcock.

Diplomas in (a) Public Health (2), (b) Psychological Medicine (8), and (c) Laryngology and Otology (5) were granted to the successful candidates whose names were printed in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of Jan. 22 (p. 134). Diplomas in Anaesthetics (27) were granted to those whose names appear in the report of the meeting published in the *Journal* of Dec. 25, 1943 (p. 835).

### ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting held on Feb. 1, with the President, Dr. A.ergus Hewat, in the chair, Dr. Donald Stewart (Birmingham) and Dr. Alexander Brown (Edinburgh) were introduced and took their seat as Fellows of the College. Dr. Duncan Macmillan (Nottingham), Dr. Richard Edward Verney (Edinburgh), and Dr. Joshua James Morris Jacobs (London) were elected Fellows. Mr. Norman I. Dott, F.R.C.S.Ed., was appointed Morison Lecturer for 1944. Dr. A. Rae Gilchrist, F.R.C.P.Ed., was appointed George Alexander Gibbon Lecturer for 1944.

### ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a quarterly meeting of the Council held on Jan. 29, with the President, Mr. Eardley Holland, in the chair, the following candidates were elected to the Membership: A. P. Bentall, Jean R. Burton-Brown, Agnes E. Cathcan, Audrey I. Freeth, D. Friedlander, M. M. Garrey, Eileen D. M. Wilson.

The Council passed a resolution of sympathy with the British Medical Association on the death of their Secretary, Dr. G. C. Anderson. The President was appointed to serve *ex officio* as a member of the Committee of Management of the Royal Medical Benevolent Fund.

### CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examinations, have been granted the diploma of L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S. Glas.:

J. M. Allan, S. Batkin, H. D. Bauer, L. Beukes, H. Bynst, F. G. Brindley, H. S. Dougal, N. R. Eaton, A. S. W. Eccerton, Jeanette R. B. Gibson, J. A. Love, C. K. Mackinnon, D. S. Mathers, W. Y. Muir, D. R. O'Keefe, J. A. Orr, P. C. C. Petters, G. L. Plester, S. M. O. Price, A. R. Ray, S. L. Schwarzwald, J. D. Scobie, J. S. M. Sililo, A. S. Smith, M. Spence, J. S. Stevenson, J. A. Sykes, Ruth R. Turner, S. Walport, J. Wilson, W. H. A. Windress, J. A. Wright.

I. Lopertas, M. Rottenberg, and E. Stengel, graduates of recognized foreign universities, were also admitted licentiates.

## Medical Notes in Parliament

### Relief in Europe: Medical Problems

The House of Commons on Jan. 25 discussed the proposals for relief and rehabilitation of the areas in Europe as they are freed from enemy control. The debate arose on a vote of credit which included expenses for relief and rehabilitation, and Sir JOHN ANDERSON explained that the Government proposed that Great Britain should contribute 1% of the national income, which would amount in round figures to £80,000,000. Mr. GREENWOOD, speaking of the enormous problems which lay ahead, said that starvation was rampant over the greater part of occupied Europe to-day, and the situation would grow worse. Increasing debility, lowered resistance to disease, epidemics of typhus, and a growing amount of tuberculosis would become more dangerous because of the large-scale forced migration which had taken place. About 20,000,000 people had been driven from their homes and countries, and a great many of them had become disease carriers. It was important to know the organization of the personnel of U.N.R.R.A. Were the doctors ready? Were there specialists for the restoration of the sanitary services?

Dr. HADEN GUEST said that although the food situation in the Middle East and North Africa had much improved, that in Italy was different and more serious, and showed the difficulties with which we should be faced. There were great food difficulties although we were in control of the area, and a raging typhus epidemic, which was difficult to control but which, fortunately, had not spread to the Allied Forces. The situation in Italy was precisely the kind which would arise in other parts of Europe, and he urged that a White Paper, dealing with the experience of relief up to date, should be published. He hoped that the voluntary relief organizations would be given, under proper supervision and after proper selection, a rather freer hand than the present Command Paper suggested. Another matter of very great importance concerned medical staffs for this work. He did not know where medical staff was to be obtained. At present we could not recruit a very large number of people from this country for medical relief work on the Continent because they were not available, but a very large number would be required for the war in the Far East. There would always be some shortage of doctors from this country, but as soon as we had got into occupied Europe many doctors belonging to the countries there would be available to give us very considerable help, and no doubt they would be willing to co-operate. He did not think the doctor difficulty would be insuperable, and he believed we should be able to control epidemics, but he hoped that what was going on in Italy would lead to a little better organization than apparently existed.

Mr. LAW said that it was impossible to estimate what the demand for voluntary workers from this country would be. At the moment the Council of British Societies for Relief Abroad was making up teams to be held in reserve against any demand from U.N.R.R.A. Those teams would, he hoped, be highly qualified. For example, there was a water purifica-

tion unit, a bacteriological unit, a static disinfector unit, and so on. It was not going to be a sort of Continental holiday for young people from Mayfair. Extremely skilled and highly qualified people would be wanted to go out and assist in the relief work in Europe.

### Army Doctors' Administrative Duties

On Jan. 25 Major CHARLES TAYLOR asked the Secretary of State for War how many members of the medical profession are employed in administrative posts in the Army or on other duties which did not involve the use of their medical skill; and, in view of the shortage of doctors, both in the Services and among the civil population, whether he would arrange for administrative posts in the R.A.M.C. to be filled by men who were not doctors. Sir JAMES GRIGG: If the question is taken literally, the answer is "None, sir"; but in view of the general shortage of doctors, a detailed investigation has been made of Army medical establishments at home and abroad. Wherever possible, officers without medical qualifications have replaced qualified medical officers employed on administrative duties, even in those posts where professional medical knowledge, although not essential, is very useful.

Major TAYLOR asked if there were not a number of cases of doctors who very rarely, if at all, used their medical skill, and who were doing purely administrative jobs in the R.A.M.C. Sir JAMES GRIGG said if Major Taylor meant purely routine administrative jobs, he imagined that the medical directors in command or in theatres of war abroad would have to be doctors, because their medical knowledge was essential for the proper administration of the medical service.

### Catarrhal Jaundice

Mr. SORESEN asked on Jan. 27 whether the Minister of Health could state the extent of the outbreak of catarrhal jaundice and to what cause or causes it was attributed. Mr. WILLINK said catarrhal jaundice was not a generally notifiable disease, although for research purposes it was recently made notifiable in certain eastern counties. He had, therefore, no definite information about its incidence. It had latterly become prevalent throughout Europe and in North Africa as well as in this country. Its causes had not been established. The Medical Research Council was making a special investigation of the disease. There was nothing to show any connexion between catarrhal jaundice and public baths.

### British Prisoners in Japanese Hands

In a statement to the House of Commons on Jan. 28 on *Japanese treatment of British prisoners*, Mr. EDEN said that in Siam many thousands of prisoners from the British Commonwealth, including India, were compelled by the Japanese military to live in tropical jungle conditions without adequate shelter, clothing, food, or medical attention. These men were forced to work on building a railway and making roads. Their health was rapidly deteriorating; a high percentage were seriously ill, and there had been some thousands of deaths. The number of such deaths reported by the Japanese was just over 100. The railway and roads concerned lead into Burma, and the conditions described applied throughout their length. One eye-witness reported of a camp in Siam: "I saw many prisoners clearly. They were skin and bone, unshaven, and with long matted hair. They were half-naked." The same witness reported that they wore no hats or shoes; and this in a tropical climate where there were practically no local resources which could provide medical or other material relief.

From Java came evidence which left no doubt that many of our prisoners were confined in camps with no adequate protection from malarial infection and lacking in proper provision for sanitation. Food and clothing provided was insufficient to maintain them in health. Reports from the northern area referred to the emaciated state of prisoners arriving from Java. In Hong Kong, Formosa, Shanghai, Korea, and Japan itself conditions generally were tolerable, although the scale on which food was provided was not adequate over long periods to maintain the health of prisoners. Conditions in Hong Kong appeared to be growing worse. In the transport *Lisbon Maru*, used to convey 1,800 British prisoners of war from Hong Kong, the prisoners were seriously overcrowded. Many were undernourished. Many had contracted diphtheria, dysentery, and other diseases. There was no medical provision, and sanitary arrangements were virtually non-existent. The vessel was torpedoed. The Japanese kept the prisoners under hatches and abandoned ship. At least 800 prisoners lost their lives. The Japanese had violated the principles of international law. The replies of the Japanese Government to the protests of the British Government, through the Swiss Government, had been evasive, cynical, or otherwise unsatisfactory.

### The Scottish Infant Mortality Report

On Feb. 1 Mr. BUCHANAN asked the Secretary of State for Scotland if he had considered the report of the committee, presided over by Sir John Boyd Orr dealing with child mortality, and what action it was proposed to take. Mr. JOHNSTON: Yes, sir. On the day of publication I invited the association of local authorities and other interested bodies to consider the report with a view to discussions which I propose to open immediately. Preliminary estimates indicate that the infant mortality rate, while still unsatisfactory, is likely to be lower in 1945 than it has ever been in Scotland.

Mr. BUCHANAN asked if there was any reason for not discussing this report, and if the Minister consulted with only one or two authorities. Mr. JOHNSTON said it was not one or two authorities. He had invited associations of local authorities which covered them all, to consider the report. It was not being ignored. It was published as early as possible, and drew the attention of the associations of local authorities to it on the date of publication.

Later in the day Mr. BUCHANAN asked the leader of the House if it would be possible to have time to discuss the report. Mr. EDEN said he had gone into this matter and found that it would be discussed on the adjournment in about a fortnight. That would give only a brief opportunity, and he had consulted the Secretary for Scotland, who felt, like the Government, that this was a matter on which they should seek to give opportunity for full discussion. He could not say, there and then, how it would be contrived, but it was the Government's wish that the report should be discussed. Perhaps Mr. Buchanan would allow the Government to make the necessary arrangements in the ordinary way.

*Mass Radiography Unit for Liverpool.*—Replying on Jan. 27 to Mr. Kirby, Mr. WILLINK said he hoped to provide a mass radiography unit for Liverpool early in May. The proportion of persons examined by mass radiography who were found to require institutional treatment was very small. He was not aware that Liverpool Corporation foresaw difficulty in this connexion in the near future having regard to the measures now being taken to increase the city's present accommodation for tuberculosis cases.

*Light Diet of Dysentery Patients in Italy.*—On Feb. 1 Colonel GREENWELL asked the Secretary of State for War if he was aware that the provision of light diet at base hospitals in Italy was insufficient for patients suffering from gastric disorders or from dysentery, and if, to rectify this state of affairs, he would consider having the relatively small quantities of foodstuffs required supplied regularly by air. Sir JAMES GRIGG: I am glad to say that the incidence of dysentery and gastric disorders in this theatre of war has been very low in recent months. It has been difficult at times to maintain an adequate supply of fresh eggs, but I do not know that there has been any other difficulty in providing suitable light diets for patients in base hospitals.

## The Services

The *London Gazette* has announced the award of the M.C. to Lieut. (War Subs. Major) A. K. Dougall, Capt. D. W. Forga (since killed in action), P. McL. Gunn, and J. W. T. Prentice R.A.M.C., and Capt. H. W. Chestnut, R.C.A.M.C. (attached R.A.M.C.) in recognition of gallant and distinguished services in Italy.

Col. (Temp.) G. A. Walsley and Capt. L. MacD. Reid, R.A.M.C. have been mentioned in dispatches in recognition of gallant and distinguished services in North Africa, and Capt. H. C. Duncan I.M.S. (seconded I.A.M.C.), in recognition of gallant and distinguished services in Burma and on the Eastern Frontier of India.

The *London Gazette* has announced the appointment as M.B. (Military Division) of Capt. L. M. Kelly, I.M.S. (seconded I.A.M.C.) in recognition of gallant and distinguished services in Burma and the Eastern Frontier of India.

Acting Surg. Cmdr. D. R. Goodfellow has been awarded the R.N.V.R. Officers' Decoration.

### CASUALTIES IN THE MEDICAL SERVICES

*Wounded.*—War Subs. Capt. A. F. Crook, B. S. Lush, J. A. Naughton, and G. H. Pickering, R.A.M.C.

*Died of Wounds.*—War Subs. Capt. W. H. Lang, R.A.M.C.

*Killed.*—Capt. D. R. Harbison, War Subs. Capt. J. L. Shan R.A.M.C.

*Prisoners of War.*—War Subs. Capt. D. O. Davies, Acting Major G. H. Garlick, Temp. Lieut.-Col. W. G. Harvey, War Subs. Capt. E. Leigh, War Subs. Capt. B. Lennox, War Subs. Capt. J. D. Lod War Subs. Capt. B. Mayne, Capt. E. A. Smyth, Acting Major F. Webster, R.A.M.C.

*Died.*—War Subs. Capt. E. M. Gamble, R.A.M.C.

No 3

## INFECTIOUS DISEASES AND VITAL STATISTICS

Print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 22.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, for: (a) The 126 great towns in England and Wales (including London) (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or return available.

Disease	1944					1943 (Corresponding Week)

\* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

± Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

## EPIDEMIOLOGICAL NOTES

## Discussion of Table

In England and Wales during the week the common infectious diseases of childhood rose in incidence: scarlet fever by 363 cases, whooping-cough by 192, measles by 102, and diphtheria by 39. There were 172 fewer cases of acute pneumonia, and 27 fewer of dysentery.

The deaths from influenza in the 126 great towns were 54 fewer than in the preceding week. The decline in Greater London, from 61 to 54, was less noticeable than elsewhere.

The rise in the incidence of scarlet fever was general, but was largest in Lancashire 51, and Yorks West Riding 62. Notifications of whooping-cough were, however, more localized; the largest increases were in Middlesex 55, Warwickshire 36, Yorks West Riding 32, and Essex 28. The rising trend of measles was mainly in the south, especially in Sussex with an increase of 55. The decline in the notifications of pneumonia was general throughout the country; the greatest decrease was in Lancashire 31, but in marked contrast to the general fall there was a rise of 36 in London.

The outbreaks of dysentery were concentrated in and around London. The largest centres of infection were London 41, Sussex 14, Surrey 12, Middlesex 11, and Lancashire 18.

Scotland reported a lower incidence for measles by 69, acute primary pneumonia by 57, scarlet fever by 43, and whooping-cough by 19, but dysentery notifications were up by 30 and diphtheria by 16. The increase in diphtheria was confined to the eastern and south-eastern areas. Two outbreaks of dysentery were reported during the week: Ayr County 12, and Dunbarton County 11. Dysentery in Edinburgh fell from 13 to 7 cases, but rose in Glasgow from 9 to 14.

In Eire measles notifications went up from 71 to 212: Dublin C.B. 94 cases, and Dublin North R.D. 100 (in an institution). Diphtheria (4 cases more) was notified from forty-two areas, and whooping-cough (22 cases more) from only six areas.

In Northern Ireland the incidence of diphtheria and scarlet fever remained high. The principal centres of infection were for scarlet fever, Belfast C.B. 64, and for diphtheria, Londonderry C.B. 17. There were 9 cases of diphtheria in a mental hospital in Omagh.

## Health Education

The *Pharmaceutical Journal* for Jan. 1 contains Ministry of Health Bulletin No. 1, the first of a quarterly series the aim of which is to use the men and women in Britain's 15,000 chemists' shops as "missionaries for health." The idea is to tell the pharmacists of the country the why and the wherefore of official health campaigns, in the hope that they will play a part in educating the public. The first bulletin, which has a foreword by Sir Wilson Jameson, contains an article by Col. L. W. Harrison on venereal disease and another on droplet infections by Dr. W. H. Bradley.

## Week Ending January 29

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,928, whooping-cough 2,104, diphtheria 777, measles 919, acute pneumonia 1,079, cerebrospinal fever 60, dysentery 176, paratyphoid 4, typhoid 2. In the great towns 104 deaths were attributed to influenza.

An appeal on behalf of the Princess Tsahai Memorial Hospital Fund has been signed, among others, by Sir Farquhar Buzzard, Lord Moran, P.R.C.P., Sir Alfred Webb-Johnson, P.R.C.S., Prof. Charles McNeil, P.R.C.P.Ed., Mr. J. W. Struthers, P.R.C.S.Ed., and Prof. John A. Ryle. During the years 1936-41 the Emperor of Ethiopia lived in this country: his daughter, Princess Tsahai, undertook training as a nurse at the Great Ormond Street Hospital for Sick Children, and after passing the examinations qualifying her to become a State-registered nurse she entered Guy's Hospital for further training. Her object was to fit herself to lead the movement for a modern medical and nursing service in Ethiopia, after its freedom had been restored. When this time came she returned to her country with the nucleus of the organization she intended to create, but her work was stopped by her illness and death at the age of 22, on Aug. 17, 1942. The present appeal is for funds to found in Ethiopia a hospital with medical school, library, and ambulance services in memory of the Princess Tsahai, and as a token of good will to Ethiopia from the people of Great Britain. It is hoped that those who are engaged in our own health and hospital services will help in this work, and that their gifts may be commemorated in some special part of the hospital. Donations may be sent to the hon. treasurer, Lord Horder, c/o Messrs. H. Reynolds and Co., 9, Greenhalgh Walk, London, N.2.

## Medical News

It is proposed to hold the Annual Congress of the Ophthalmological Society of the United Kingdom on Friday, March 31, and Saturday, April 1, at the Royal Society of Medicine, Wimpole Street, W. There will be two subjects for discussion: the first, at the Friday morning session, is "Ocular Psychoneuroses (excluding Miner's Nystagmus)," and will be opened by Mr. R. C. Davenport and Squad. Ldr. J. H. Daggart. The second, at the Saturday morning session, is "Virus Affections of the Eye," and will be opened by Prof. A. Sorsby and Dr. C. H. Andrewes. Part of the Friday afternoon session will be devoted to a joint clinical meeting with the Ophthalmological Section of the Royal Society of Medicine.

A paper on "The Art of Cooking Vegetables" will be given before the Royal Society of Arts, John Adam Street, Adelphi, W.C.2, by Miss Phyllis L. Garbutt, A.I.C., on Wednesday, Feb. 16, at 1.45 p.m.

The "Radio Doctor" will deal with "What is Immunization?" in his broadcast talks in the "What is it?" series in the B.B.C. Home Service at 7 p.m. on Sunday next, Feb. 13.

A Diagnosis Section meeting of the Faculty of Radiologists will be held at 32, Welbeck Street, W., on Saturday, Feb. 19, at 10 a.m., when there will be a discussion on lung abscess.

The following meetings of the British Institute of Radiology will take place at 2.30 p.m. in the Reid-Knox Hall, 32, Welbeck Street, London, W.: Friday, Feb. 18, meeting of medical members. Saturday, Feb. 19, ordinary meeting, at which Dr. Norman P. Henderson will read a paper on the value of the opaque cinema and its modifications.

A sessional meeting of the Royal Sanitary Institute is to be held at Bournemouth on Feb. 19, when the morning will be devoted to papers on "Health Education at Infant Welfare Centres and War-time Nurseries" by Dr. Vida Stark and on "Food Hygiene of Hotels and Restaurants" by Mr. W. Riley, senior sanitary inspector of Bournemouth. After lunch, which is at the invitation of the Mayor and Corporation, there will be a visit to Linford Sanatorium, near Ringwood. Further information may be had from the hon. local secretary, Dr. H. Gordon Smith, Town Hall, Bournemouth.

An extension of the Limb-fitting Centre at Queen Mary's (Roehampton) Hospital will be opened on Tuesday, Feb. 22, by His Excellency the Chinese Ambassador, Dr. Wellington Koo. After the Minister of Pensions has expressed thanks to the Governors for providing the extended building Dr. R. Langdale Kelham will show a film, with commentary, and there will be a demonstration by patients of the use of artificial limbs.

At a meeting of the Eugenics Society on Tuesday, Feb. 22, at 5.30 p.m., in the Rooms of the Royal Society, Burlington House, Piccadilly, Mr. B. S. Bramwell will give an address on "The Order of Merit: the Holders and their Kindred."

Twelve clinical demonstrations in neurology in connexion with the course of instruction for a diploma in psychological medicine will be given at Maida Vale Hospital for Nervous Diseases, London, W.9, at 3 p.m., on Feb. 29; March 9, 16, 23, and 30; April 4, 13, 20, and 27; and May 11, 18, and 25. The fee for the series is three guineas, paid in advance, cheques being made payable to the London County Council and forwarded to Dr. W. W. Kay, acting hon. director of the Maudsley Hospital Medical School, Central Pathological Laboratory, West Park Hospital, Epsom, Surrey, to whom inquiries regarding the course should be addressed.

The following meetings of the Royal Sanitary Institute will be held next month at 90, Buckingham Palace Road, S.W.1, at 2.30 p.m. On March 1 Mr. P. G. Shute will read a paper on "Indigenous Malaria and Mosquito Control in England after the War"; on March 15 Sir William Savage will open a discussion on "Current Questions of Milk Supply"; and on March 28 Mr. A. Longworth will speak on "Rational Design of House Plumbing."

The Association of Scientific Workers (Hanover House, 73, High Holborn, W.C.1) announces that Prof. P. M. S. Blackett, F.R.S., has been appointed its president from Feb. 1, 1944.

Mr. W. C. W. Nixon has been appointed Medical Representative to the British Council in Turkey.

The prices of all brands of unmodified and modified insulin are to be reduced on Feb. 14, when a new schedule of prices will come into operation.

A new Order prohibits nurses in mental hospitals and institutions in Scotland from leaving their employment without the consent of the employing authority. This brings practice in Scotland into line with that in England and Wales.

Dr. T. Chalmers Borthwick, late of Ichang, China, has been reported a prisoner of war in Japanese hands.

## Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal*, alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (room 9, a.m. to 5 p.m.). Members' subscriptions should be sent to the Secretary of the Association.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES—EDITOR, *Atiology Westcent, London*; SECRETARY, *Medisera Westcent, London*. ADVERTISEMENTS, *Articula Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

### ANY QUESTIONS?

#### Post-partum Haemorrhage

**Q.**—*Post-partum haemorrhage seems to be much more frequent lately, even after easy labour. Several of my colleagues with whom I have discussed this matter are of the same opinion. (1) Is there any explanation? Could it be due to deficiency of diet? (2) Can any measures be suggested which might be adopted during pregnancy to lessen the risk of such an alarming event? (3) Intravenous ergometrine has been found an excellent remedy, but is no longer obtainable. Is it safe to give pitocin intravenously in urgent cases? What dose is advised?*

**A.**—Reference to the statistics of a maternity hospital dealing with over 3,000 "district" and "in-patient" deliveries per annum does not reveal any significant change in the incidence of post-partum haemorrhage during the last ten years. (1) If there is an increase dietetic deficiency is an unlikely cause. The degree of malnutrition would have to be gross. An increased use of anaesthetics should be borne in mind as a possible explanation. (2) Prophylactic measures recommended are: calcium lactate 30 to 40 gr. daily during the later months of pregnancy; quinine hydrochloride 1 gr. t.d.s. during the last 2 to 3 weeks of pregnancy; pitocin 0.25 c.cm. intramuscularly; or stilboestrol 0.5 mg. by mouth twice daily for 1 to 2 weeks before delivery. (3) Pitocin may safely be given intravenously in a dose of 0.1 to 0.2 c.cm. (1 to 2 units). In emergency, as much as 5 units has been given without ill effect, but so large a dose involves the risk of reaction, because pitocin is not entirely free from vasopressor factor.

#### Effect of Cervicectomy on Pregnancy

**Q.**—*A patient aged 35 already has two children aged 9 and 7. After the birth of the second child she had the following operation—amputation of cervix and anterior colporrhaphy for cystocele. No further pregnancies were considered owing to poor general health. She is now much improved and anxious to have another child. Is it correct that the chances of pregnancy are much less after such an operation, and that, should she become pregnant, early interruption—abortion or premature labour—is likely? Is recurrence of cystocele probable?*

**A.**—Conception is not impaired by a previous plastic repair if this has been wisely and skilfully performed. If a high amputation of cervix has left the patient with practically no vaginal cervix there is an increased risk of early abortion. This risk could be minimized by taking special care during the week of the suppressed period for the first 3 to 4 months: excessive weariness, travelling, strong purges, and intercourse should be avoided. The injection of 5 mg. of progesterone would also be helpful once or twice during this week. If in the second stage of labour an episiotomy is performed, a great deal of the tension on the previous repair is relieved and the chance of recurrence is correspondingly reduced. To summarize: if a prolapse has been effectively repaired there is no reason why a subsequent pregnancy should not occur and be satisfactory.

#### Fröhlich's Syndrome

**Q.**—*What is the best line of treatment for a girl of 11½ years suffering from Fröhlich's syndrome?*

**A.**—The triad of Fröhlich's syndrome is adiposity, failure of sexual development (primary and secondary sexual characteristics), and dwarfism. The diagnosis, however, can be correctly made if only the first two features are present. Very often, however, the diagnosis is incorrectly made when adiposity is the only feature and sexual development is normal, slightly delayed, or (especially in the case of the boy) obscured by adiposity. It is difficult to diagnose Fröhlich's syndrome in a girl of 11½ years, since puberty may not occur in normal individuals until a later age than this. Where sexual development is lacking, it may be stimulated by gonadotropic hormone.

the male, pregnancy urine extract is effective. In the female, this would be combined with the follicle-stimulating hormone of pregnant mare's serum, or with the follicle-stimulating hormone of bovine pituitary glands. The adiposity is treated on the usual lines, with diet and thyroid. Should dwarfism be a feature, pituitary growth hormone is advisable if the epiphyses are ununited.

#### Mixing Pertussis Vaccine and Diphtheria Prophylactic

Q.—I am using the pertussis vaccine (Intel) for immunizing infants against whooping-cough. Since this is carried out at about the same age as the immunization against diphtheria, is there any objection to mixing the pertussis vaccine and the A.P.T. together in the same syringe and giving it as one injection? I am using the dosage suggested by you—viz., three injections of 1.0, 1.0, and 2.0 c.m. of 20,000-million-organisms-per-c.c.m. vaccine with a week's interval between the first and second injections and a month between the second and third. If the vaccine and A.P.T. can be mixed, the A.P.T. could be incorporated in the second and third injections (giving a month's interval) and thus avoid two further injections.

A.—But is immunization against pertussis best carried out at the same time as against diphtheria? Pertussis attacks and kills many babies in the first few months of life: therefore immunization should be begun early. On the other hand little diphtheria is recorded under the age of twelve months; and, moreover, some children do not develop immunity satisfactorily if injected with diphtheria prophylactic much before their first birthday. Few authorities practise immunization of children against diphtheria until the twelfth, or at the earliest the ninth, month. On the point of mixing, it is probably true that prophylactics made in the same way and containing the same antiseptic may be mixed without loss of efficiency—e.g., T.A.B. and those founded on it. But it cannot be accepted that different prophylactics—e.g., a toxoid and a vaccine containing different antiseptics—can be mixed for a short or longer time before injection with perfect safety and without the possibility of some unexpected effect on the prophylactics (Bousfield has called attention to this point.) The reputable manufacturer, to be sure of his ground, would mix the two prophylactics—in this case diphtheria and pertussis—and then apply to the mixture the same tests for proof of protecting power as had been applied to the separate constituents. And that raises the question: What tests of protecting potency had been applied to the batch of pertussis vaccine? McFarlan and Elizabeth Topley in the November *Monthly Bulletin* of the E.P.H.L.S. report an investigation in which the pertussis vaccine used had afforded no protection. They suggest that the vaccine may have been inefficient or the dosage may have been too low; no data were available about its power to protect mice or produce antibodies in human beings. One would guess from the excellent figures for protection in several campaigns in the U.S.A. that at least some of the pertussis prophylactics used there would protect mice and produce antibodies. Until such vaccines are generally available in England perhaps the questioner would hold his hand.

#### A Complicated Case

Q.—A lady aged 65 has had rheumatoid arthritis for some 10 to 15 years, mainly in the fingers, wrists, toes, and knees. A few years ago I found she was also suffering from pernicious anaemia. This has much improved with intramuscular liver injections. In the past month she has developed severe pruritus and vulvae, spreading down the inner side of the legs, and recently she has become more sensitized—with areas of dermatitis on the thighs and arms. I have tried her on various remedies. Would oestrogen help? There is no local cause to be found in the anal canal or vagina. She has no vaginal discharge; urine is normal—no sugar, no albumin.

A.—The answer to this question can be divided into three separate items: (1) Rheumatoid arthritis and pernicious anaemia, it may be assumed, must have some effect on the other states, but only indirectly. (2) Pruritus vulvae et al. is usually responsive to small doses of x rays. (3) The dermatitis or eczema will best be relieved by rest and simple local applications, such as ichthyol 2% in oily calamine. Some form of sedative is called for. Oestrogen treatment may be tried, although there is no constructive indication for its use. This case appears to present one of those complex and difficult problems where the practitioner can often plan out treatment by drawing up a sort of schedule on a sheet of paper and working out separately the symptoms and their remedies.

#### Ergotamine Tartrate for Migraine

Q.—What is the mode of action of ergotamine tartrate in removing the headache of migraine? Is it useful for other forms of headache? Is there any danger in long-continued use or increase of dosage? I have used it by injection as the oral route is not effective.

A.—It seems likely that ergotamine tartrate removes the headache of migraine by causing vasodilatation in the cerebral blood vessels, which results in increased cerebral blood flow. Whereas ergotamine causes vasoconstriction in vessels elsewhere in the body, workers in Heymans's laboratory in Ghent showed that in the head ergotamine

caused vasodilatation. Ergotamine tartrate is now known to be useful for other forms of headache. There is danger in too frequent use of the drug, for it causes gangrene of the extremities. It was formerly used in obstetrics, and cases are on record in which its administration was accidentally continued for a long period and resulted in gangrene. It is impossible to say what intervals should elapse between doses—probably a week. Ergotamine is not inactive by mouth, but the onset of its action by mouth is slow and gradual, the earliest effect appearing 20 minutes after the drug is taken.

#### "Bowel-consciousness"

Q.—Why does the tongue get furred in the constipated?

A.—In a healthy subject who is constipated there is no furring of the tongue. Many conditions, ranging from minor visceral neuroses and dietetic indiscretions to acute fevers with dehydration and gastro-enteritis, may be responsible for the association, but the furred tongue is no more the result of the constipation than the constipation is the result of the furred tongue. The successful propaganda of patent medicine firms has made the public over-conscious of its bowel habits, and the poor appetite and unpleasant gastro-intestinal symptoms of many patients with constipation are tributes to its powerful influence in provoking a psychosomatic disorder. If doctors and nurses were to make a determined effort to defeat the ill effects of these unfortunate advertisements there would probably be far fewer people who "suffered" from constipation.

#### Destruction of Vitamin C
